Atlanta Georgia

THE objective measurement of blood flow has interested innumerable investigators. Many methods while crude, have contributed to our understanding of the circulation. With the development of more exact instruments for such evaluation, the appraisal of circulatory disturbance has become more critical. These studies not only supplement clinical evaluation of the patient, but permit a more objective evaluation of symptoms, circulatory insufficiency, and results of various forms of therapy.

Investigation of circulatory physiology by instruments has previously been concerned with alterations in skin temperatures, changes in the volume of the extremity determined by the rate and volume of blood flow as measured by the plethysmograph, and dimensional pulsation of mass as determined by the oscillogmeter. These observations, while of value reveal little in regard to the adequacy of the circulation in maintaining normal metabolism in the tissue of the extremity.

In man the flow of blood in the extremities is largely concerned with two factors: (1) the metabolic demands of the tissues and (2) the regulation of body temperature. Since sepa-

rate requirements of both are to be satisfied it would be suspected that the mechanism of their individual accomplishment would be different. The effective circulation in the muscles of the extremities is dependent upon the flow of blood through the capillaries. In this manner the metabolic demands of the tissues are supplied and the waste products are moved.

Temperature regulation, on the other hand, is basically dependent upon variations in rate and volume of blood flow through the superficial channels. Suckert and H. H. H. described the neurovascular glomeruli in man occur chiefly in the distal extremities. These structures effect arteriovenous anastomoses by permitting anastomosing between the terminal arteries and the veins of the extremities. When these anastomoses open an increase in the skin temperature results. Harpuder and others have shown that when blood is shunted through such arteriovenous channels a deprivation of blood flow through the nutrient capillaries results and tissue metabolism may be adversely affected. Therefore a rise in skin surface temperature is not an indication of an increase in the nutritional efficiency of the circulation in a part. Similarly changes in volume of the extremity as measured by the plethysmograph are to be expected with the opening of the

This work was supported in part by the Medical Department, United States Army and by the United States Public Health Service.

arteriovenous shunts. Other methods which are concerned with observation of changes in the blood flow in the skin have similar limitations.

Blumgart and Weiss in 1927 utilized radioactive substances in the study of the velocity of blood flow. Their method consisted of injecting an active deposit of radon into the antecubital vein of one arm and detecting its arrival in the opposite arm with a shielded cloud chamber. The radioactive substance used in these studies was radium B and its products in equilibrium. Although it rapidly decayed with a half life of 26 minutes the residuum persisting with disintegration was radium D which is also a radioactive isotope of lead with a half life of 22 years. This isotope is deposited in bone and produces a prolonged radiation effect.

With the availability of other radioactive isotopes which are more satisfactory for use as tracers additional methods for the study of the circulation have been developed. Smith and Quimby Musson (11, 12) and others have used sodium 24 as a tracer in evaluating circulatory diseases of the extremities. Sodium 24 possesses many characteristics which make it particularly suitable for such studies. It has a short half life (14.8 hours) and is not selectively absorbed by any tissues. It is relatively rapidly excreted and is nontoxic to tissues. Its freedom from long lived radioactive contaminants and its radiation spectrum make it harmless when used in small amounts. The quantity used in these studies resulted in a radiation to the body of considerably less than 1 roentgen. With the method employed the radiation effect was even less significant. The emissions from the radioactive sodium consist of hard beta and gamma rays. The gamma rays are easily detected and recorded by electronic equipment placed outside the body.

ELECTRONIC APPARATUS

For this investigation it was necessary to design an instrument which would permit accurate evaluation of radioactive tracers in studies of the circulation. Quantitative measurement of the radiation from sodium 24 in the tissues was made with an apparatus employing Geiger Mueller tubes which operate an electromechanical system to record auto-

matically and continuously the counts as detected by each tube (Fig. 1).

The Geiger Mueller tube its quenching circuit and a cathode-follower amplifier are enclosed in a lead cylinder (Fig. 2). The thickness of lead eliminates about 50 per cent of the radiation from sodium 24 directed at the counter. Although this would not be satisfactory for taking counts in the presence of strong extraneous or scatter radiation, little difficulty was encountered in these investigations. The gamma radiation is admitted to the Geiger Mueller tube through a window formed by removal of a portion of the lead wall. This aperture is covered by a thin aluminum shield. The detector is therefore close to the source of the radiation, resulting in a high rate of count from the area.

With this equipment it is possible to operate four counting circuits simultaneously. These can be used to record counts from one two or three locations, a remaining circuit being used to record background and scatter radiation. The advantages of such a multiple system in circulatory investigations are evident, but would be offset by the confusion of taking data if an automatic recording system were not employed.

Pulses from a Geiger Mueller tube are fed into a Lifschutz (9, 10) scaling circuit which accepts and "stores up" 32 counts before recycling. A special electronic circuit translates the total number of counts accumulated by a scaler into a current which activates the pen of the mechanical recorder. Figure 3 shows the record that is made using this system. The "steps" in the figure indicate single counts, while each peak indicates every thirty-second count. At increasing rates where the individual counts disappear, interpolation of the number of counts is made possible by pre-adjustment of the translating circuit to give a deflection of one chart unit per count. At still higher rates, the inertia of the pen makes full swings impossible. At such rates individual counts are of no consequence. Each peak on the chart then indicates the reception of 32 counts. It can be seen that instantaneous changes in counting rates are indicated clearly by a definite change in the slope of the mounting curve. Thus the time at which radioactive material reaches a Geiger Mueller detector can be determined to the second.

A method employing electronic integrating circuits driving graphic pen recorders was tested but several weaknesses of this system proved it to be unsuitable for this study.

Four detectors containing Geiger Mueller tubes are connected by flexible cables to a control panel on the wall of the examining room. From this point the cables extend through an electrical conduit to an adjoining room in which the recording circuits, amplifiers and power supplies are located. The injection

Designed by R. H. Rohrer, Assistant Professor of Electrical Engineering, Emory University and W. B. Miller, Jr., Electronics Consultant for the Department of Surgery. This circuit is described in an article "A Method of Automatically Recording Slow Random Counts," to be published.

Fig. 1. Electromechanical apparatus used for automatically recording impulses received from the Geiger Mueller tubes.

time of the sodium is indicated on the record by means of a foot switch in the examining room.

METHOD

Radioactive sodium carbonate is received from the pile at Oak Ridge Tennessee. The mass obtained weighs 0.3 gram and is rated 35,110 milliroentgens of gamma radiation per hour at 24 inches from source of gamma radiation. This material is converted into sodium chloride by the addition of hydrochloric acid. Neutralization is effected by titration with sodium hydroxide. The resulting sodium chloride solution is evaporated to dryness and

is redissolved in pyrogen free distilled water, and sterilized by autoclave. Dilutions of the material are made depending upon the proposed method of utilization.

Two methods of study were employed one, described by Smith and Qumby (12) involves the 'build up' of radioactive sodium in the tissues of the extremities following its intravenous injection in the arm. The second is a relative flow determination based on the rate of disappearance of radioactive sodium when injected intramuscularly, as suggested by Kety. It is obvious that the first method depends not only upon the flow of blood to

Fig. 2. The detector unit for reception of impulses from the radioactive sodium in the tissues.

the part but also upon the diffusion of the sodium chloride from the vessel into extravascular spaces. The second method is concerned with the mobilization of the sodium which has been injected into the muscle and

its removal from extravascular spaces by the effective circulating blood.

Method 1 Intravenous injection of radioactive sodium. The patient was placed upon a tilt table in a room in which the temperature was constantly controlled at 78 degrees F. The legs were elevated at an angle of 35 degrees (Fig. 4). A detector was placed posterior to each gastrocnemius muscle and at the ball of each foot. Prior to administration of radioactive solution the background count from cosmic rays and other extraneous radiation was recorded by the equipment.

Five cubic centimeters of the prepared solution containing one to two hundred microcuries of radioactive sodium was rapidly injected intravenously in the antecubital vein. The time and duration of injection was recorded. The syringe was removed from the room immediately following injection of the solution.

The circulation time to the leg was determined by the sudden rapid increase in the rate of count (Fig. 3). The circulation time to the foot could not be accurately determined in all instances due to a gradual increase in concentration of sodium at this point. This increased concentration resulting from the establishment of an equilibrium of the isotope between the intravascular and extravascular spaces was recorded over a period of 30 to 45 minutes.

Fig. 3. Chart as recorded by the electronic apparatus. Single counts are indicated by the horizontal lines. Vertically curved lines represent intervals of 5 seconds. The marker indicates the time and duration of injection of the radioactive sodium intravenously.

Ninety individuals were studied by this method. Sixty of these had no demonstrable vascular disease. The curves plotted from their record formed an average pattern (Fig 5). The persons observed, both male and female, varied markedly in build, muscular development, height, weight, age, obesity, and skeletal size. The amount of radioactive sodium injected was recorded. It was found that an unsatisfactory build up curve resulted if less than 80 microcuries was injected. The variation between curves depended more upon the amount of sodium injected than upon any of the above factors. Therefore, in subsequent observations following the injection of drugs, or operation upon the vascular or sympathetic nervous systems, an identical amount of sodium was employed for comparative results.¹

With this method of study, the random radiation from various portions of the body imposed an exceedingly difficult factor, and a marked increase in background count for each tube necessitated extensive shielding of the Geiger Mueller detectors.

Method II The injection of radioactive sodium into the muscle. Utilizing the same apparatus, studies were made following the injection of sodium directly into the gastrocnemius muscle. The solution was diluted so

Miss Mary H. Atkins was technician for this project.

Fig 4. Position of patient on tilt table with legs elevated. Detector units are placed at the site of injection of the radioactive sodium.

that each cubic centimeter contained 100 microcuries. The patient was placed either in a horizontal position or with the extremities

Fig 5. Buildup curves in the tissues of the extremity following the intravenous injection of radioactive sodium chloride in normal individuals.

Fig. 2 The detector unit for reception of impulses from the radioactive sodium in the tissues.

the part but also upon the diffusion of the sodium chloride from the vessel into extravascular spaces. The second method is concerned with the mobilization of the sodium which has been injected into the muscle and

its removal from extravascular spaces by the effective circulating blood.

Method I Intravenous injection of radioactive sodium The patient was placed upon a tilt table in a room in which the temperature was constantly controlled at 78 degrees F. The legs were elevated at an angle of 35 degrees (Fig. 4). A detector was placed posterior to each gastrocnemius muscle and at the ball of each foot. Prior to administration of radioactive solution, the background count from cosmic rays and other extraneous radiation was recorded by the equipment.

Five cubic centimeters of the prepared solution containing one to two hundred microcuries of radioactive sodium was rapidly injected intravenously in the antecubital vein. The time and duration of injection was recorded. The syringe was removed from the room immediately following injection of the solution.

The circulation time to the leg was determined by the sudden rapid increase in the rate of count (Fig. 3). The circulation time to the foot could not be accurately determined in all instances due to a gradual increase in concentration of sodium at this point. This increased concentration resulting from the establishment of an equilibrium of the isotope between the intravascular and extravascular spaces was recorded over a period of 30 to 45 minutes.

Fig. 3 Chart as recorded by the electronic apparatus. Single counts are indicated by the horizontal lines. Vertically curved lines represent intervals 15 seconds. The marker indicates the time and duration of injection of the radioactive sodium intravenously.

Ninety individuals were studied by this method. Sixty of these had no demonstrable vascular disease. The curves plotted from their record formed an average pattern (Fig 5). The persons observed, both male and female, varied markedly in build, muscular development, height, weight, age, obesity, and skeletal size. The amount of radioactive sodium injected was recorded. It was found that an unsatisfactory build-up curve resulted if less than 80 microcuries was injected. The variation between curves depended more upon the amount of sodium injected than upon any of the above factors. Therefore, in subsequent observations following the injection of drugs, or operation upon the vascular or sympathetic nervous systems, an identical amount of sodium was employed for comparative results.¹

With this method of study, the random radiation from various portions of the body imposed an exceedingly difficult factor and a marked increase in background count for each tube necessitated extensive shielding of the Geiger Mueller detectors.

Method II. The injection of radioactive sodium into the muscle. Utilizing the same apparatus, studies were made following the injection of sodium directly into the gastrocnemius muscle. The solution was diluted so

that each cubic centimeter contained 100 microcuries. The patient was placed either in a horizontal position or with the extremities

Fig 5. Buildup curves in the tissues of the extremity following the intravenous injection of radioactive sodium chloride in normal individuals.

Fig. 6. Rate of disappearance of radioactive sodium when injected intramuscularly. Increase in rate of disappearance is indicated by vertical inclination of the line.

elevated and with a detector posterior to the superior portion of each gastrocnemius muscle. A third counter was placed at a short distance from the subject to record background radiation.

A volume of 0.2 cubic centimeter of this solution containing approximately 20 microcuries of sodium 24 was injected into each gastrocnemius muscle. In this study the exact amount of radioactive material injected was of no significance nor was it necessary to inject an identical amount into each calf muscle since the rate of disappearance as evidenced by the decrease in counting rate was the factor to be determined. The patient was constantly observed to insure the immobility of the extremities.

Following injection the recording apparatus was operated for a period of 12 minutes prior to any alteration in the conditions of the

experiment. After the initial or control run various procedures could then be carried out, such as application of a tourniquet, the administration of drugs, the performance of sympathetic blocks, etc. After the procedure was performed the subject was returned to the original position and an additional 12 minute run was made to determine the effect of the therapy on the circulation of the extremities.

Since the amount of sodium injected into the muscle was small no difficulty was encountered as a result of radiation from the opposite extremity or from other parts of the body. Similarly following the mobilization of the sodium into the vascular system and its distribution throughout the body the amount of sodium returning to the extremity through arterial channels was so low that background radiation was not increased.

It is apparent that this method of injecting the sodium directly into the muscle and recording its subsequent removal by the effective circulating blood permits an objective evaluation of the effective blood flow through the nutrient capillaries. While such a determination alone does not allow an exact estimation of blood flow per given muscle mass at this time values are obtained which will permit accurate comparison.

DISCUSSION

In both of these methods it was found desirable to elevate the extremity approximately 35 degrees above the horizontal. A stress factor was thus imposed which accentuated the degree of vascular insufficiency. Elevation in the normal individuals produced no changes in the disappearance rate. It has long been appreciated that pallor of the extremity on elevation is one of the simplest tests for vascular insufficiency. Buerger, Brooks, Homans and others have emphasized that the rapidity with which color returns to the digits of the elevated extremity upon compression indicates vascular sufficiency.

By the intravenous injection of radioactive sodium the recording of its arrival time in the extremities and the subsequent build up of the sodium in the extravascular spaces (method I) the circulation time to the extremities can be accurately determined.

The variations in the circulation time to the extremities found in normal individuals is so wide as to render these results valueless in the diagnosis of circulatory disorders. The arrival of the radioactive material at the part and the subsequent increase in concentration is dependent upon many uncontrollable factors. A measurement is not necessarily being made of the presence of the sodium in the larger arteries but more accurately of that which has escaped into the extravascular fluids.

Through accurate standardization of the quantity of radioactive sodium administered for repeated determinations, comparative data can be obtained on the rate of increase in sodium concentration in the tissues of the extremities. This rate of increase is to a degree proportionate to the volume of blood flow to the extremity. An accurate determination of actual muscle blood flow as differentiated from flow to the various other tissues cannot be determined by this method however. It also has a disadvantage in that it does not immediately reflect changes in the state of circulation in the extremity following the injection of drugs, therapeutic procedures, alterations in position of the extremity or the utilization of mechanical devices which are devised to improve the blood flow.

With injection of radioactive sodium directly into the muscle and the measurement of its rate of disappearance (method II) it is believed that a valuable method of determining the relative effective blood flow to the muscles has been obtained. It is apparent that the rapidity of removal of the sodium from the muscle depends upon the volume of blood flow.

When the results of this method are plotted on semilogarithmic paper with the number of counts per minute plotted on the ordinate and the time on the abscissa, a linear expression of the rate of disappearance of the sodium from the muscle is obtained (Fig 6). The inclination of this line will remain unchanged while the conditions of this experiment are not altered. If the removal of sodium is prevented by the application of an arterial tourniquet above the site of injection the line will become horizontal (Fig 7). As the rate in which the sodium is removed from the muscle increases

Fig 7. Application of tourniquet prevents removal of radioactive sodium as represented by a horizontal line. Following release of tourniquet the resulting hyperemia removes the sodium more rapidly than normal with a more vertical line being obtained. Equilibrium is established as indicated.

the line will tend to become vertical. After removal of the tourniquet hyperemia results in a more rapid removal of sodium, the normal rate being resumed only after disappearance of the period of hyperemia.

It is believed by Kety that a logarithmic expression of the slope of the line is valid for comparative studies. This expression or 'K' factor is the natural logarithm of the slope of the line and is determined by the equation

$$K = \frac{\log C_1 - \log C_2}{.4343 (T_2 - T_1)}$$

C_1 = counting rate at time T_1
 C_2 = counting rate at time T_2

This latter method has been utilized in 115 individuals both normal and with vascular disease. It has been used in normal individuals to evaluate the effect of certain drugs and other measures reputedly effective in enhancing the circulation in the extremities. Similarly it has been used in the evaluation of patients with vascular disease and their response to therapy. These observations are to be reported at a later date.

SUMMARY

1 Two methods for the use of radioactive sodium 24 in the investigation of circulatory physiology of the extremities are compared and discussed.

2 The apparatus is described in detail.

3. The results of one of the methods used in a series of normal individuals are evaluated (The results of the other method are to be published later)

OBSERVATIONS ON PRODUCTION OF PERICARDIAL ADHESIONS AND LIGATION OF CORONARY ARTERIES

ALEX W BOONE M D and DAVID S HUBBELL, M D., Durham North Carolina

CLINICAL and laboratory investigation directed toward surgical establishment of collateral circulation to myocardium was pioneered by Claude S Beck (1-7) Three general methods have been used O Shaughnessy (16) brought an omental graft to the heart from the abdominal cavity through an incision in the diaphragm Beck (5) used transplants of pectoral muscle Several authors (10 11 13 14 16, 17) have produced adhesions between myocardium pericardium and epicardial fat believing that this procedure might offer a feasible method of approach

It has been assumed that if anastomoses can be established between vessels of the pericardium and those of the myocardium, augmented circulation would occur that would partially alleviate anoxia of coronary insufficiency Moritz and associates (14) using injections of colloidal lamp black have shown that extracardiac anastomoses of branches of the coronary artery are increased by pericardial adhesions O Shaughnessy (18) also demonstrated that vascular connections will develop between vessels of myocardium and adherent or adjacent structures They used histological and injection studies

Irritating substances have been applied to the epicardium or injected into the pericardial sac during operation to produce adhesions (21) Materials usually employed (20 23) have been inconsistently effective or have produced pleural effusion foreign body granulomatous reaction or damage to the heart Work by Heimberger indicates that certain detergents would produce adhesions with minimal side effects Further studies have been undertaken to evaluate materials for production of adhesions and also function of the heart after adhesions Rats dogs and one hog were used

EXPERIMENTS

For convenience experimental studies will be described in three groups group I formation of adhesions, group II effect of adhesions group III effect of adhesions with coronary occlusion

GROUP I FORMATION OF ADHESIONS

Method The materials to be tested were introduced into the pericardial sac of white rats through thoracotomy wounds Operations were performed positive pressure ether anesthesia and aseptic surgical technique were used Six substances commonly employed by others and reported effective for production of pericardial adhesions were injected into the pericardial sac of 42 white rats Also various dilutions of 13 detergents were similarly injected into the pericardial sac of 94 rats As a control saline alone was injected into the pericardial sac of 10 rats Also a 5 per cent solution of monoethanolamine oleate was introduced into the pericardial sac of one hog by means of parasternal injections without thoracotomy

Observations Autopsies on the control series of rats sacrificed 14 to 25 days after operation and injection of normal saline revealed no adhesions Substances usually employed by others and listed in Table I produced adhesions inconsistently Three of them, talc lycopodium and asbestos produced foreign body reaction (granulation) and one talc produced pleural effusion Among the 13 detergents used (Table II) 9 produced damage to the heart and occasionally death even in dilutions of 2.5 per cent Three did not produce adhesions Adhesions involving at least one-third of the pericardium were produced by 10 detergents used Foreign body reaction was not produced by detergents and soaps but some caused pericardial or pleural effusion Ubiquitous adhesions with good vascularity were formed in the hog (Fig 1)

From the Department of Surgery and the Department of Pathology Duke University School of Medicine.

Fig. Subacute adhesions in dog's heart 35 days after injection of monoethanolamine into the pericardial sac. Above the thickened vacuola pericardium are seen well developed cavels 5 to 60 micra in diameter fibrosis, and light infiltration of plasma cells and leucocytes.

Of the materials employed for injection monoethanolamine oleate in a 5 per cent solution seemed to be the most efficacious and the least toxic. It was therefore employed to produce adhesions in the rats and dogs used for subsequent experiments.

GROUP II EFFECT OF ADHESIONS

Possible effects of adhesions were studied by means of physical efficiency tests in rats and venous pressures and electrocardiograms in dogs. Adhesions were produced in the rats used for these experiments by intrapericardial injection of 0.2 cubic centimeter quantities of monoethanolamine oleate and in the dog by

injections of 5 cubic centimeters. Relative physical efficiency was tested in rats by forced swimming with 15 grain weights tied to the tail. All animals were sacrificed and examined post mortem after the period of tests for gross and microscopic study of the adhesions.

Observations. Table III summarizes the effects of pericardial adhesions upon physical efficiency of rats, as determined by the swimming test. There was no significant change of swimming time after formation of adhesions. In Table IV observations on the effect of adhesions upon venous pressure of dogs are tabulated. There was little change either during the first month or up to 4 months. The electrocardiogram of dogs failed to show evidence of constrictive pericarditis, although in one instance 4 months following the formation of adhesions some decrease in amplitude was observed.

All animals were sacrificed after the test periods to determine whether evidences of altered circulation were present. None showed evidence of chronic passive congestion. The morphologic changes following pericardial injection of monoethanolamine oleate in the rat and the dog varied chronologically into three stages.

1 *Acute* The first stage lasting 7 to 10 days was characterized by presence of fibrin polymorphonuclear leucocytes and round cells on the epicardial and pericardial surfaces. Although little effusion was observed in rats approximately 10 to 15 cubic centimeters of fluid was often found in the pericardial cavity of dogs. Evidence of fibrosis or of vessel proliferation was not found during this stage.

2 *Subacute* The subacute phase lasted about 10 to 24 days in the dog and rat and was present at about 35 days in the dog. It was characterized by gradual disappearance of fibrin and development of light fibrous connective tissue joining the two serous surfaces (Fig. 2). Most interesting and important was the development of communicating blood vessels which appeared at this time. These vessels were well formed, dilated capillaries for the most part, with lumina about 12 to 60 micra in diameter and full of blood. Some of the vessels had a thin outer coating representing adventitia and possibly muscularis. Most however were smaller.

3 *Chronic* In the third the chronic stage little was seen except a moderately thickened, adherent, fibrotic pericardium with little cellularity or vascularization.

GROUP III EFFECT OF ADHESIONS AND CORONARY OCCLUSION

Methods Ligation of the anterior descending branch of the left coronary artery was performed through a thoracotomy incision using

Fig. 2 Rat heart with subacute vascular adhesions. Above the intact myocardium is seen the vascular thickened epicardium-pericardium adhesions with well formed capillaries. The subacute inflammatory process seen on the outer surface of the pericardium is the result of leakage that occurred in many of these rats after injection.

No. 6-0 silk in the rat and No. 3-0 silk in the dog. Swimming time in the rat and electrocardiograms and venous pressures in the dogs were employed to test the effects of ligation alone and of ligation and adhesions. The effect of coronary occlusion produced prior to or up to 1 month following formation of pericardial adhesions was studied in rats. A series of dogs

was also studied in which coronary ligation was performed alone or following the formation of pericardial adhesions.

Observations. The extent of decrease of swimming time following coronary ligation is illustrated in Table V. It is evident that a significant decrease in relative physical efficiency occurred after ligation. Infarcts developed in the myocardium of the left ventricle of each rat (Fig. 3).

In a series of 8 rats ligation of the left coronary artery was followed within a few days by

injection of the pericardial sac and production of adhesions. Swimming times were obtained 1 month later; results are summarized in Table VI. In 6 rats adhesions were produced 1 month after coronary ligation. Swimming times were obtained before ligation 1 month later before re-injection to produce adhesions and 1 month after adhesions (Table VII).

The venous pressures of 2 dogs to be treated by ligation of their coronary arteries averaged 16.7 centimeters of water before operation. One and 2 months after ligation their pressures averaged 15.0 centimeters of water. Ligation of the left coronary artery was performed in 4 dogs 10 to 24 days after injection of the pericardial sac during the stage described above as subacute or having vascular

Fig 4 Myocardial infarction in the dog heart produced, a, left in the presence of the early subacute stage of pericardial adhesions, and, b in the absence of pericardial adhesions.

adhesions. This effected a change of venous pressure from an average of 16.7 centimeters before ligation to 24.5 centimeters during the first several days afterward.

Electrocardiograms obtained before and after coronary artery ligation in each of the above two groups of experiments revealed changes of pattern characteristic of anterior infarction.

Autopsy revealed large infarcts in the wall of the left ventricle of each of the above dogs. Typical infarcts are presented in Figure 4. The microscopic appearance of these infarctions and of adhesions produced 4 weeks or more before autopsy are presented by a representative section (Fig. 5).

OBSERVATIONS

Experiments have indicated that monoethanolamine oleate in 5 per cent solution when injected into the pericardial sac of the rat, dog or hog produces good adhesions without undesirable side effects. Adhesions are fibrinous for 7 to 10 days then fibrous and avascular another 10 to 35 days and subsequently fibrous and avascular.

Adhesions themselves produce no change in relative physical efficiency of rats as determined by swimming times or by venous pres-

ures or electrocardiograms of dogs during 1 to 4 months of observation. Autopsies revealed no evidence of constrictive pericarditis or of passive congestion.

Ligation of the anterior descending branch of the left coronary artery in rats produced

Fig 5 Avascular fibrotic pericardium characteristic of the chronic stage of pericarditis in the dog. Scarring of the myocardium; evidence of an old infarction, is seen above. At 4 o'clock is a bit of suture material.

infarction of the muscle of the heart wall with reduction of relative physical efficiency as evidenced by decreased swimming times. In jection of the pericardial sac a few days after ligation did not change this decrease of swimming time. Adhesions produced a month or more after coronary ligation did not produce significant increase of swimming time. The slight increase shown in column 3 of Table VII could be explained by gradual improvement in function of the heart after the ligation and would probably occur even though the adhesions were not present.

Ligation of the coronary artery of dogs during the subacute or vascular stage of adhesions was followed by typical infarction and by some heart failure as judged by increase of venous pressure.

Pericardial adhesions evidently neither alleviate the diminished function following coronary ligation nor hasten recovery. Neither do they effect a significant reduction in the size of myocardial infarcts. There were however fewer changes in the postligation electrocardiograms of those dogs having pericardial adhesions before ligation.

CONCLUSIONS

1. These studies have not yielded evidence to support treatment of patients with myocardial ischemia by production of pericardial sac adhesions.

2. Blood vessels that appear 7 to 10 days after production of adhesions are replaced within a month by avascular scar tissue.

PRINCIPLES OLD AND NEW OF RESECTION OF THE COLON FOR CARCINOMA

LELAND S McHITTRICK, M D F.A.C.S Boston Massachusetts

SINCE the first successful resection and anastomosis of the bowel for carcinoma by Reybord in 1832 the problem of removal of a segment of bowel and restitution of continuity has been a continuing challenge to all abdominal surgeons. It shares with all other surgical procedures the improvement in results following the many advances in the care of patients that have occurred in recent years, tending I believe more nearly to standardize the surgical treatment of cancer of the colon than has been possible before.

I am intentionally avoiding a statistical approach to this problem but rather have chosen to review the more important contributions through the application of which the writer has developed his present concept of the management of these cases. I am intentionally limiting this discussion to resection of the colon for cancer because this involves the dual problem of proper treatment of the cancer and the technical aspect of resection and anastomosis. I am excluding the lower segment of the large bowel, which has been treated by combined abdominoperineal excision or by anterior excision with a permanent colostomy.

LYMPHATIC SPREAD

As I see segments of bowel resected for carcinoma which have been brought to the laboratory I cannot but conclude that in many instances the surgeon has been so concerned with the technical aspect of re-establishing continuity that the primary problem of curing the patient of his cancer has been neglected.

The primary objective of an operation for cancer is complete eradication of the disease. If complete resection is to be accomplished it must be foremost in the surgeon's mind and the operation planned must have this as the primary objective. To plan an adequate resection presupposes an understanding of the vas-

cular supply to, and lymphatic drainage from the colon with particular reference to the amount of tissue which is to be removed if the patient is to have the optimum opportunity of cure.

In 1909 Jamieson and Dobson, after careful study of prepared specimens presented an excellent description of lymph drainage from the various segments of the colon. They called attention to the line of first defense, the so-called paracolic glands located along the arcades on either side of the lesion and of the concentration of the drainage from these into the intermediate glands situated between the arcades and the origins of the colic and sigmoidal vessels, all of which are removed in an adequate surgical excision (Fig 1). On a basis of this study, they suggested the amount of tissue which should be removed in order to offer the proper protection from lesions in the several segments of the bowel (Figs 2a, b, and c).

The recent work of Gilchrist and David on the lymphatics of the rectum and of Collier, Kay, and MacIntyre on the colon would seem to have definitely established certain additional facts. (1) By the time the patient is operated upon, more than half of the lesions (rectum 69 per cent, colon 60.8 per cent) will have metastasized to the regional nodes. (2) Metastases may occur without gross changes in the nodes be unnoticed by the surgeon and demonstrated by the pathologist only after the application of special techniques. (3) While the normal flow of lymph coincides with the direction of venous return, an alteration of flow will result and metastases may occur in a retrograde direction if a given lymph channel is blocked. (4) The size of the local lesion is no criterion as to the presence or absence of nodal metastases.

The practical application of these studies to amount of tissue to be removed at operation will be discussed later.

Fig. Showing arterial supply and distribution of more important lymph nodes. The celiac nodes on the wall of the bowel are considered of lower importance and are not shown.

DEVELOPMENT OF TECHNIQUE OF RESECTION AND ANASTOMOSIS

The observations by Lanfrank in 1396 and Travers in 1812 that healing of the intestines to the parietal peritoneum and to each other came through the agglutination of the serosal surfaces, followed in 1826 by Lambert's description of a method of suture which would hold in apposition the serosal surfaces of two segments of bowel to be united represent the earliest contributions to intestinal resection. Little of significance followed until 1892 when two contributions of great importance appeared in the literature—the introduction of the anastomosis button by John B. Murphy

and the description by Oscar Bloch of an entirely new approach to the problem by the extra abdominal removal of a segment of bowel. Murphy in describing his anastomosis button said: "If means can be devised—1st to hold the surfaces in contact 2nd while in contact to produce a speedy and permanent adhesion of the surfaces 3d to keep an opening sufficiently large for the free passage of intestinal contents 4th to produce as a result a cicatrix that will not contract to any great extent and by the contraction produce complete or partial obstruction—we will have overcome the great barriers remaining between us and ideal success in intestinal surgery."

Fig. 2. a, Segments of bowel to be removed for carcinoma of cecum, left, and hepatic flexure, right, as suggested by Jamieson and Dobson. b, Segments of bowel to be removed for carcinoma of splenic flexure, left, and descending colon right, as suggested by Jamieson and Dobson. c, Segments of bowel to be removed for carcinoma of sigmoid, left, and rectosigmoid, right, as suggested by Jamieson and Dobson.

In that same year Bloch in Norway, discouraged by the high mortality following primary resection of the bowel for cancer (he gives reports from various clinics showing mortality rates of from 47 to 59 per cent), conceived an operation whereby peritonitis

could be avoided by doing the actual resection of the bowel outside of the abdominal cavity. A short (6 cm.) incision was made just above and parallel to the inguinal ligament. A long loop of sigmoid with the carcinoma at its apex was withdrawn through this wound and anchored to the wound at either end, an opening was made in the mesentery well away from the growth through a relatively avascular area where there were no enlarged nodes and a glass spatula put through this (Fig. 3). Two sutures were placed on either side of the bowel approximating the afferent and efferent loops. A rubber tube was placed in the proximal segment for relief of the obstruction. One month later the bowel and mesentery were divided and an attempt was made to do an extra abdominal anastomosis between the two ends. This anastomosis failed. The patient was discharged 6 weeks later, remained well, gained in health, and returned after 2½ months.

(about 5½ months following the original operation) At this time an end to-end closure was done in the wound. The anastomosed segment of bowel was then freed and replaced in the peritoneal cavity. The patient had a relatively uneventful convalescence was discharged and died at a later time of metastatic cancer of the liver.

Three years later Mr F T Paul surgeon to the Liverpool Infirmary apparently unaware of the work of Bloch describes 7 cases from which he evolved a logical finished concept of the management of cancer of the large bowel. The presentation of these cases is an excellent example of orderly thinking and warrants brief comment. His first case—a woman of 49 with obstruction and vomiting due to cancer of the sigmoid was operated upon a very favorable growth removed and a difficult anastomosis carried out by invagination on the decalcified bone. Death the night of operation was thought to be due to a long difficult operation as well as to the slight leakage which was found at postmortem. The next case—a woman of 47 entered with complete obstruction due to a large carcinoma of the sigmoid. A right lumbar colostomy was done to relieve the obstruction. Ten days later the growth was resected. The operation was difficult and the patient's condition too poor to warrant suture of the ends of the bowel so that they were brought out through the wound as had been done on previous occasions by a number of other surgeons. This patient died at the end of 36 hours and Paul makes the following note: "I consider that the loss of this case was due chiefly to a want of appreciation of the profound and prolonged effect of a serious attack of intestinal obstruction partly to the absence of sufficient technical skill." His third case—a 47 year old woman with a cancer of the cecum also had a resection and what he considered a very satisfactory anastomosis by the bone tube method. This patient also died of peritonitis, which he thought might have been due to restriction of too much blood supply. And in discussing this death he makes the following note: "The sloughing of the cut end of the colon would probably have taken place with any mode of approximation but had it been outside in

stead of inside the peritoneal cavity the small area of gangrene would have done no harm. His fourth case—a woman of 60 ill with acute obstruction of 9 days duration was operated upon through a left inguinal incision. The sigmoid with the obstructing lesion was withdrawn through the wound the bowel was clamped a portion of the bowel containing the growth was excised and a glass intestinal drainage tube was sutured into each end of the bowel. The dressing was then applied and the proximal end of bowel permitted to drain into a basin. This patient made an uneventful convalescence and died 2 years later at which time postmortem examination failed to reveal any evidence of recurrent disease. This operation was done in May 1892. Mr Paul noted:

One might conclude that when the excision was not too extensive and the ends of the bowel brought out correctly it might be undertaken with comparatively little danger to life. Case 5—a patient of 38 without marked obstruction was operated upon for a carcinoma of the descending colon. The bowel was freed from the splenic to the sigmoidal flexure the mesentery carefully tied ligated and divided the bowels brought out through the wound and the glass tubes inserted. This patient too made an uneventful convalescence. Paul was not content however to permit this patient to go through life with a permanent colostomy and 5 weeks after the original operation an attempt at closure of the colostomy was carried out. The patient died of peritonitis 4 days later. Paul in reviewing this case expresses his disappointment at having evolved a method of resecting a tumor safely only to have the patient die in attempting to avoid a permanent colostomy. He then makes the following interesting statement:

"There remained however to be tried the old plan of restoring continuity by Dupuytren's enterotomy to which very little risk is attached. If such a method could be perfectly successful when the spur was accidentally formed by nature how much more ought it to be so when a spur was deliberately constructed with the object of being subsequently safely removed? I have therefore, brought out and determined to put in practice the following method of operating in the next case. First, excise the strictured portion of bowel as in the last 2 cases then suture together the cut edges of the mesentery and the adjacent sides of the two ends of the colon in

such a manner that they would adhere together for about 3 inches, in the position of two barrels of a double barreled gun. If this succeeded the spur might be demolished without the slightest risk of peritonitis and to such an extent as to insure a free passage and easy closing of the artificial anus (Fig 3)

His next case done according to this concept had the growth removed and the colostomy successfully closed. In the final case reported the patient died following operation before the anastomosis was carried out. Death was due to uremia, as proved by autopsy. There was no peritonitis and the two parallel limbs of bowel which he had sutured were well healed. It is of interest that Paul's final conclusions formed on a basis of these experiences were

"When the patient is in good condition the abdomen not distended the tumor small and the proximal end of the bowel not greatly hypertrophied I advise immediate approximation by Murphy's button method. But when the opposite of these conditions prevails I strongly urge that the ends of the bowel should be brought out in the manner explained and illustrated and I feel sure though I have been an unfortunate in the sort of cases I have had to deal with that this method of bringing out the ends is much safer than any other plan of immediate approximation all statistics notwithstanding

It need only be added that Mikulicz in 1903 referring to Bloch's work but making no reference to that of Paul described and strongly advocated the exteriorization type of operation. His plan was to mobilize the bowel divide the mesentery to include removal of regional nodes bring the loop through the wound close the abdominal wall apply a dressing, and remove the growth in 12 to 48 hours or immediately (Fig 3). A tube was placed in the proximal segment. He did much to popularize this procedure and to bring it before the English speaking world particularly the surgeons of this country through his writing and particularly through its inclusion in a system of surgery published in this country in 1904 (2).

This procedure was brought to its highest state of perfection by Rankin in his article Obstructive Resection published in 1930. Without question the development and utilization of the principles involved in these procedures represent the greatest single contribu-

tion to the safety of resection of the large bowel that has been made.

The early frequent wound recurrences due to inadequate operation, which often followed the exteriorization procedures and the long period of disability stimulated surgeons to continue their quest for safer methods of primary anastomosis. In the gradual evolution of this method, certain serious hazards were recognized. Of greatest significance was the rôle of obstruction so well expressed by Paul in his article and stressed so much by the many writers in this country. It is impossible to know to whom credit should go for insistence upon proper attention to the obstructed bowel and particularly to the development of the importance of relief of obstruction through proximal decompression. Again it is of interest that Paul in 1891 did a right lumbar colostomy as a preliminary procedure in a patient with acute obstruction upon whom a diagnosis of cancer of the left colon had been made (Case 2 above). Jones Cheever Rankin, Whipple (19) Bevan, and many others advocated and repeatedly stressed the importance of proximal decompression until it was accepted by most surgeons of experience as an essential part of resection with primary anastomosis. Proximal decompression for resection of the colon probably reached its highest state of development with the use of the Miller Abbott tube as described by Whipple (20).

In the earlier days of direct anastomosis outstanding contributions were made by the development of simple and safe methods whereby anastomosis could be carried out with closed bowel thus avoiding the dangers of contamination from the open ends of the transected intestine. Of the many methods described the writer has preferred that of Parker and Kerr whose anastomosis utilized the principle of a hasting stitch rather than instruments. It has proved to be simple, useful and safe.

Stone and McLanahan in 1939 stressing the importance of the closed anastomosis recognized the diminishing need for proximal decompression and may well have ushered in the modern era of safe intestinal anastomosis without its use except in selected cases with obstruction.

TABLE L.—TYPES OF OPERATION AND MORTALITY RATES—1932-1941

	Number	Deaths	Mortality rate %
Anastomosis with proximal decompression	40	6	15
Anastomosis without proximal decompression			0
Obstructive resection	3		0
Right colectomy one stage	5	3	60
Right colectomy two stages	30		5
Totals	90	9	

PRINCIPLES GOVERNING SAFE ANASTOMOSIS

Along with the development of safer methods of suture and the acceptance of proximal decompression certain basic principles were stressed as essential or of great importance in the completion of a safe and proper operation. Thus Bevan in 1920 was governed by three basic principles: (1) proper selection of incision; (2) free mobilization of the bowel in relation to the growth; and (3) the use of a lateral rather than end-to-end anastomosis. The writer during his long association with D. F. Jones constantly heard stressed the importance of three fundamental principles in any intestinal anastomosis: (1) adequate blood supply; (2) avoidance of excessive intra-abdominal pressure through proximal decompression; (3) avoidance of any tension at the suture line.

Improved methods of anesthesia and a better understanding of the many aspects of patient care have resulted in such improvement in results following all major surgical procedures that we may now revise our thinking in relation to intestinal resection bringing together experiences of the past with the developments of the present.

We might then present what we consider to be the essential basic principles for resection of the colon for cancer:

1. Proper preparation of the patient for operation.
2. Optimum exposure of the segment of colon to be excised.
3. Adequate mobilization of bowel.
4. Adequate cancer operation.
5. Free blood supply to both segments.
6. Avoidance of tension on suture line.
7. Proximal complete colostomy if adequacy of suture line or blood supply is in doubt.

Preparation of the patient. The name of Rankin more than any other one surgeon is associated with careful and adequate preoperative preparation of any patient who is to be operated upon for cancer of the large bowel. Only in recent years, however, has the real importance of this become apparent to all surgeons. We customarily require from 5 to 10 days, or more of hospital care in preparation of a patient for resection. Just how long proper preparation will take is dependent upon a number of factors relating to the degree of obstruction and the general condition of the patient. Rather than state the time involved one might better state the objectives to be obtained. Unless repeated hemorrhage or some other complication prevents every effort should be made to have the patient go to operation with a deflated empty well prepared bowel. He should be well nourished, with a serum protein level and hemoglobin within normal limits, and have had an adequate or excess vitamin intake. In the absence of more than a mild degree of obstruction this is accomplished by the use of an active cathartic on the afternoon of admission (our preference is for castor oil but any active cathartic is satisfactory) sulfasuxidine or sulfathiazidine (the former if there is any degree of obstruction) for a minimum of 5 days; a low residue diet containing from 100 to 125 grams of protein daily; the use of some potent polyvitamin in excess of the normal needs; and blood transfusions to bring the hemoglobin to within normal limits. The use of the scout film to determine the amount of material in the bowel proximal to the lesion is very helpful. It has been our experience that patients with mild to moderate obstruction will empty out their bowels in a completely satisfactory way following the use of sulfasuxidine and small divided doses of a saline cathartic if sufficient time is allowed. In those patients who cannot be otherwise adequately prepared, particularly in those patients with complete obstruction, some form of proximal decompression is necessary. In the completely and acutely obstructed patients, it is our policy to do a cecostomy under novocaine suturing a half inch rubber tube into the distended cecum by several infolding sutures. If after release of the acute

obstruction the bowel cannot be satisfactorily prepared either through spontaneous restoration of bowel activity or the use of irrigations through the cecostomy tube with the Miller Abbott tube as suggested by Millett a transverse colostomy is done. This is placed to the right of midline if the splenic flexure is to be mobilized otherwise, in or to the left of midline. As will be noted proximal surgical decompression has been used in only a small proportion of cases in the recent years (Table II).

We now use the Miller Abbott tube in preparation for operation only on certain indications. If the patient has a large, full abdomen or a tendency to slight distention the Miller Abbott tube is started 48 hours before time of operation in the hope that it may be well into the lower small bowel at the time of resection. This not only provides proximal decompression but the fluting of the bowel on the tube markedly increases the freedom with which the operative procedure can be carried out. In those cases in which the Miller Abbott tube is not to be used the Levin tube is inserted into the stomach the afternoon before operation and placed on suction in order to eliminate all swallowed air from the intestinal tract for a period of 12 to 18 hours before the time of operation. This insures a deflated stomach and does lessen the amount of gas that will be found in the small bowel.

Incision. Experience with various types of incisions in patients who have been operated upon has convinced me that the only important consideration in the selection of an incision is the amount of exposure which is given throughout all aspects of the proposed operation. The incision most frequently used for resections in the right half and the left half of the colon is a long right or left rectus muscle splitting incision. This is particularly useful on the left where as will be later shown most resections involve mobilization of the splenic flexure above and an anastomosis which may frequently involve working with the distal sigmoid in the lower abdomen. The transverse incision gives excellent exposure for a resection and anastomosis of the transverse colon. In general an incision placed parallel to the long axis of the bowel to be resected

TABLE II — TYPES OF OPERATION AND MORTALITY RATES—1942-1947

	Number	Deaths	Mortality rat %
Anastomosis with proximal decompression.	12	2	16.6

Right colectomy two stages	6	1	16.6
Total operations	129	7	5.4
Total resections with primary anastomosis	110	4	3.6

will afford optimum exposure of that particular segment.

Adequate mobilization of bowel. We have become increasingly convinced that Bevan's insistence upon adequate mobilization of the bowel is one of the most important factors in resection of the left colon. Except for the occasional lesion which we find at the apex of a long loop of sigmoid or for the lesion in the lower sigmoid it is our policy to mobilize the splenic flexure and a portion of the transverse colon in all cases. If the incision is properly placed and of sufficient length if the dissection is started in the region of the sigmoid or descending colon and carried up around the splenic flexure, mobilization of the splenic flexure (unless there is a large tumor in that area) is not difficult nor is it hazardous. Not only is this necessary in order to do an adequate operation for many of the lesions in the left colon but the increased mobility of the upper and lower segments of bowel makes it possible to bring the ends to be joined into the wound outside of the abdomen, insuring freedom of action and complete absence of tension on the line of sutures. It is our feeling that this procedure has contributed more to the safety and to the ease of left colectomy than has any other single maneuver.

Adequate cancer operation. In Figures 4 and 5 are shown the segments of bowel which we believe should be removed for cancers located in the various segments of the colon in order to give the patient the best chance of permanent cure. It is recognized that this is a schematic presentation and that abnormalities in blood supply or physical set up will frequently make impossible the carrying out of what we believe to be the theoretically correct procedure. It

Fig. 4. Schematic representation of segments of bowel and mesentery which should be removed for carcinoma of rectum. *A-B* hepatic flexure, *A* splenic flexure *C-C'* and descending colon, *C-D*

is nevertheless surprising how frequently one can approach the ideal if that is the major objective of the surgeon particularly if the concept of complete mobilization is accepted. A very free anastomosis between the vessels and presumably also the lymphatics above the level supplied by the superior hemorrhoidal artery makes it desirable at least on the theoretical basis, to remove a long segment of normal bowel and mesentery below the margin of the growth as well as above. We prefer a minimum of 3 inches of normal bowel and accompanying arcade of vessels and lymphatics on either side of the lesion with inclusion of the lymphatic drainage to as high a level on the primary branches of the superior or inferior mesenteric arteries as local conditions will permit.

Blood supply. There can be no question but that the importance which Jones placed upon

adequate blood supply cannot be overestimated. Primary suture in the absence of a completely adequate blood supply will result in leakage and unless there is proximal diversion of the fecal stream severe sepsis or death may occur. Normally and probably in many instances the free collateral exchange between the various branches of superior and inferior mesenteric arteries will insure adequate supply over a long segment of bowel even if primary branches are divided so long as the arches are left intact. Nevertheless, surgeons and students of the blood supply to the large bowel are aware of the many anomalies which exist and it is our judgment that assurance of adequate blood supply is not to be based upon a knowledge of what the anatomy should be but upon an actual visualization of pulsating or bleeding vessels at the margins of divided bowel to be anastomosed. If we cannot see actual pulsating vessels so situated as to insure blood supply to the cut end it is our policy to transect intentionally a small vessel before a clamp is applied in order to visualize free arterial bleeding. Only under these conditions can one be assured that anastomosis can be safely carried out.

Avoidance of tension. Too often surgeons forget that sutures merely represent a method of holding in approximation the segments of bowel to be joined. They are not a means of bringing together two segments under tension and temporarily keeping them in place. Any two ends of bowel which are to be united must lie in easy approximation and be completely free from tension.

Complimentary transverse colostomy in selected cases. Those surgeons who have had wide experience with the abdominoperineal excision of the rectum are aware of the tremendous variation in the amount of blood carried to the rectum through the middle hemorrhoidal arteries. Many times these vessels are cut during the course of the dissection without the necessity of applying ligatures. Other times they are large freely bleeding vessels supplying a large amount of blood to the segment in question. If therefore the superior hemorrhoidal vessels have been divided as they should be divided for lesions whose lymphatic drainage accompanies these

vessels, it will frequently happen that the blood supply to the upper rectum to which the sigmoid must be joined will be questionable or it may be that under this circumstance there has been difficulty in properly placing the sutures and the surgeon may not have the complete confidence in the technical phase of the anastomosis that he would like. Under these conditions it is our feeling that a loop of transverse colon should be brought out through a separate incision in the upper abdomen and the fecal stream completely diverted from the line of anastomosis. If such a procedure is carried out it is then essential that before closure of the colostomy the line of anastomosis be carefully examined by means of barium enema to determine whether or not there is a leakage around the suture line. If such leakage does occur and it not infrequently will the closing of the colostomy must be postponed until healing is complete and in any of these cases we have seen up to the present time healing has occurred spontaneously in 1 to 3 months.

TECHNICAL CONSIDERATION

Right colon We have never used the exteriorization operation on the right colon. In the occasional cases in which patients cannot be properly prepared for a one stage procedure we have used preliminary ileotransverse colostomy followed in 16 to 21 days by resection. In this type of case, we prefer lateral anastomosis in continuity to transection of the ileum. For many years following the teaching of D. F. Jones we used the lateral anastomosis in our one stage procedures. This is probably the simplest and safest type of anastomosis that can be done. If the blind ends are short they do not give symptoms and the functional results are completely satisfactory. More recently, we have been doing an open end to-end anastomosis. Although the functional result is no better than when the lateral anastomosis was used the anatomical result is superior and there is only one suture line to put in. If the lateral anastomosis is used the medial side of the mesentery is closed before the anastomosis is carried out. If the end to-end junction is employed it is easier to do the anastomosis first closing the mesentery after the anasto-

Fig. 5. Schematic representation of bowel and mesentery to be removed in carcinoma of transverse colon at apex of long mid-loop of sigmoid, A-A and lower sigmoid or rectosigmoid, A-B.

mosis is completed. The lower portion of the right gutter is closed in all cases, but only rarely can it be closed throughout its entire length. Drainage is not employed unless there is persistent oozing or an abscess cavity has been broken into. Proper drainage is then instituted into the retroperitoneal area through the right flank.

Midtransverse and left colon Wide acceptance of the exteriorization operations was probably the greatest single factor in increasing the safety of resection of the left colon. It has made possible safe intestinal resection in the hands of experienced and less experienced surgeons. However there are definite disadvantages in this type of operation and with the present development of patient care and technical surgery I feel certain that these operations will rapidly diminish in popularity. I personally have done but one in the last 6 years. I feel concerned at times lest our res-

TABLE III.—RESECTIONS WITH PRIMARY ANASTOMOSIS CAUSES OF DEATH—1942-1947

Operation	Age	Cause of death	Comment
Resection of transverse colon	78	Ket Larva	Palliative operation—extensive local disease
Resection of recto-sigmoid and resection of sigmoid	78	Shock—a cause found (autopsy)	
Resection of sigmoid		Peritonitis (clinical)	Palliative operation—extensive local disease

dent staff at the Massachusetts General Hospital not know the technique of this procedure as it is now so rarely used in that institution.

The operation of choice for the writer in a lesion at or beyond midtransverse colon is an adequate removal of the bowel and mesentery with a direct end-to-end anastomosis. My own preference is for a closed type of anastomosis,¹ using the Parker Kerr technique. We prefer the basting stitch to the use of instruments since in our hands it is more flexible. It is always available and can be used lower in the pelvis than instruments. We have personally had no difficulty in the formation of a diaphragm or with any other form of obstruction at the site of the anastomosis. Care is taken not to narrow the diameter of the bowel during the placing of sutures and to be sure that the diaphragm is adequately broken down after the basting stitches are removed. We use a No. 1 plain catgut for the basting stitches, a continuous No. 000 chromic catgut suture for the inside and interrupted No. 70 cotton for the outside layers. When possible the suture line is protected by means of omental tabs or by means of omentum. Drainage is not used unless there is some specific indication as suggested above. The mesentery is always carefully closed medially but when the left colon is completely mobilized the remaining bowel falls back into the raw area in the left gutter and no attempt is made to close this with peritoneum.

There is an increasing trend toward use of

¹The closed anastomosis is not suitable method after resection for diverticulitis, nor do we use it in anastomosis of small bowel.

open anastomosis and the recent report of Allen Welch and Donaldson gives support to the safety of this method. It is not the method but the care with which the operation is carried out that is of major importance.

I do not use chemotherapeutic or antibiotic agents locally or systemically. It is my feeling that if the requirements for direct anastomosis have been fulfilled and the operation has been carefully done the anastomosis will function properly; there will be no leakage and there is little danger of peritonitis. If the blood supply is inadequate or if the sutures have not been properly placed there will be leakage and serious results may follow. Bactericidal agents will not compensate for either. I am not convinced that intestinal antiseptics play as important a part in intestinal surgery as does careful preparation of the bowel and of the patient as already discussed. While I do use sulfasuxidine or sulfathalidine in the preparation of the bowel before operation I still consider the bowel contents as actively infectious as though no drug were used. I hold but one thought—restoration of bowel continuity through a carefully done anastomosis independent of any other help.

Postoperative care. The postoperative management of these patients is very simple. A transfusion of 500 cubic centimeters of whole blood is usually given on the table during the course of the operation. If there has been undue blood loss during the procedure additional blood is given to replace the loss. The patient is allowed liquids without milk or fruit juices during the early period of healing aware that the line of anastomosis is probably weakest at the end of about 4 or 5 days. On the fifth day milk is allowed in the diet. Following that it is rapidly built up to an adequate diet low in residue. The rectal tube is inserted at frequent intervals to permit the release of any gas which might collect in the rectum. Morphine or pantopon is given freely for any discomfort. Supplementary fluids are given by the parenteral route if the oral intake has not been adequate and it usually is not for the first 3 or 4 days. Vitamins C and B complex group are given intravenously in 5 per cent glucose in distilled water or in saline as the indications may be. One thou-

sand cubic centimeters of 5 per cent amigen or its equivalent in dextrose is given daily for 4 or 5 days. A hematocrit or hemoglobin determination is made 48 hours after operation. If the hemoglobin is below 13 grams per 100 cubic centimeters sufficient blood is given to bring it above this level. If the Levin tube has been used we rarely leave it in place more than 48 hours after operation because of the inability of the patient to utilize fluids taken by mouth with the tube in place. If the Miller Abbott tube has been used and is well down the patient can be given fluids as desired and will utilize them. If the patient tolerates the tube well it is left in place until gas is being passed freely by rectum. If on the other hand, the patient is greatly bothered by the tube, we have no hesitancy in removing it after 24 hours. We do not use sulfasuxidine after operation. In most cases the bowels will move spontaneously by the sixth day, if they do not move by this time, milk of magnesia, 10 cubic centimeters every hour for 3 doses, is given. The patient is usually discharged 10 or 11 days after resection.

RESULTS

The immediate results following resection of the colon for cancer are given for the past 16 years, the year 1942 being used as the transition year from the earlier to the present methods (Tables I and II). More striking than the drop in mortality rate is the transition from staged operations to resection and primary anastomosis, proximal decompression being reserved for those who were admitted with advanced obstruction or where a difficult anastomosis had been performed low in the pelvis and there was some doubt as to the security of the suture line. The mortality rate of 3.6 per cent for the 110 operations in which a primary anastomosis was done seems to justify a continuance of the present methods.

Discussion of fatal cases following primary anastomosis (Table III). The 2 patients who died following resections for extensive local and metastatic disease need no comment. The 78 year old woman, whose sigmoid growth had intussuscepted, who was operated upon with obstructive symptoms and without proper preparation, and for whose death no adequate

cause was found, should probably not have had a primary resection with anastomosis. Better judgment might well have avoided this fatality. The fatal pulmonary embolism occurred in a young woman with a somewhat difficult low anastomosis. Autopsy showed necrosis of a short segment of the suture line which had spontaneously healed by agglutination of the open area to adjacent structures. Quite possibly this local fault contributed to the formation of the fatal thrombus. This represents either a technical error or error in judgment in not recognizing the possible faulty anastomosis and performing a proximal colostomy.

SUMMARY

Several of the more important contributions to resection and anastomosis of the colon for cancer have been reviewed.

Principles for resection and primary anastomosis are presented.

Results following resection in the decade before 1942 and in subsequent years are given.

The trend toward resection with primary anastomosis is shown and mortality rates given which would seem to justify this change.

THE EFFECT OF HEPARIN ON WOUND HEALING

E. MEREDITH ALRICH M.D., and EDWIN P. LEHMAN M.D., F.A.C.S.
Charlottesville Virginia

IN 1940 in this laboratory evidence was presented by controlled experiments that heparin will prevent the reformation of peritoneal adhesions (5). It was postulated that this effect is due to the prevention of the formation of fibrin in the peritoneum into which fibroblasts could grow. If heparin has this effect in the peritoneal healing process, a similar effect might occur in wounds by the prevention of the formation of a fibrin scaffold for fibrosis with resulting delay in the increase of wound strength. Since heparin is used freely in postoperative cases any such result should be known. The work herein reported was interrupted by the war and only recently completed.

Murray in 1938 pointed out that heparin apparently did not inhibit the healing of incisions in blood vessels, although no measurements were made. Bendix studied the effects of heparin on the healing of gastric incisions finding no effect on the fifth postoperative day. Laufman and Heller in 1943 reported no essential difference between the tensile strength of abdominal incisions in dogs receiving heparin postoperatively and a comparable group of control animals. Several investigations have shown an inhibitory effect of heparin on growth of embryonal and tumor tissue in culture media (2, 3, 7).

METHODS

In these experiments, rabbits were used weighing 5 to 7 pounds. Under nembutal anesthesia and aseptic precautions, a right rectus incision was made. The stomach was brought up into the incision and a segment of the anterior gastric wall grasped with an atraumatic clamp. The anterior gastric wall was incised for a distance of 2.5 to 3.0 centimeters, and the incision was closed with two layers of fine cotton. A Connell stitch was used for the

inner layer and interrupted mattress sutures for the outer. The abdominal incision was then closed in three layers, with three continuous fine cotton sutures—one for the peritoneum and posterior rectus fascia, one for the anterior rectus fascia, and one subcuticular stitch for the subcutaneous tissue and skin.

Two series of animals were followed, one control and one experimental. The operative procedure was identical in all of the animals. All were fed a standard laboratory diet, including green leafy vegetables, and received 100 milligrams of vitamin C subcutaneously each day beginning with the day of operation. The experimental group received $\frac{1}{2}$ cubic centimeter of heparin¹ intravenously and 1 cubic centimeter subcutaneously immediately after the operative procedure, following which they were given 1 cubic centimeter of heparin subcutaneously every 4 hours until the time of sacrifice for wound testing. It was found that this massive dose of heparin was required to assure continuous and marked prolongation of the coagulation time in the animals from the time of closure of the abdominal wall to the time of wound testing.

Plasma proteins were determined by the micro-Kjeldahl method on each animal preoperatively and at the time of sacrifice.

Groups of animals in each series were sacrificed at intervals of 2 days beginning with the second and ending with the fourteenth postoperative day. The stomach wound was tested by excising the stomach, ligating the orifices, and inflating it with compressed air until rupture occurred either through the wound or in the normal stomach wall. The pressure in millimeters of mercury at the time of rupture and the site of rupture were recorded. One centimeter strips across the abdominal incision including all the layers of the abdominal wall and the contained suture

²cc Toronto units per c.

Fig 1 Wound tensile strength, individual and average. Black dot, control average; circle, experimental average.

material, were tested by suspending the strips between two clamps and adding weight at a constant rate until disruption occurred. The disruption weight was recorded in grams. Two or more one centimeter strips from each animal were tested, and the average of these several values was taken as the tensile strength of the wound. Since the continuous sutures were divided at each border of the test strip they pulled out without influencing the breaking strength of the wound. The data obtained were subjected to statistical analysis in the case of the abdominal wounds.

Numerous animals died on the first to fourth postoperative day: 17 out of 40 or 42.5 per cent, in the experimental series and 7 out of 35 or 20 per cent in the control series. In the control series the causes of death were the effect of anesthesia or hemorrhage from

cardiac puncture done to collect preoperative blood samples, while in the experimental series death occurred from these two causes as well as hemorrhage from the gastric wound, although careful hemostasis was carried out. No animals that showed gross evidence of hemorrhage either in the general state of the animal or by pathologic findings were used in the evaluation of wound healing in either the control or experimental series. The control group contained 27 satisfactory animals and the experimental, 23.

RESULTS

The tensile strengths of the abdominal wounds (individual and average) for the control and experimental series are shown for each time interval in Figure 1. The average tensile strength of the abdominal wounds of

the control animals at each interval is 200 to 1 000 grams stronger than that of the corresponding wounds of the experimental animals from the sixth through the fourteenth postoperative day. The individual wounds at each time interval of testing in the heparinized series are in general of lower tensile strength than are those in the control series, although the strongest wounds in the experimental series at each time interval are stronger than the weakest wounds in the corresponding control groups with the exception of the tenth postoperative day.

The results for the gastric incisions are shown in Table I for the control and experimental series. In the control series of 27 animals, there are 14 which ruptured at the gastric incision while 13 ruptured at some point other than the incision. In the experimental series

of 22 animals, there were 16 which ruptured at the gastric incision while 6 ruptured at some point other than the incision. In considering the animals at the twelfth and fourteenth day none of the stomachs in the control series ruptured at the incision. However all of the stomachs at the corresponding days in the experimental series, with the exception of 2 in the 14 day group ruptured at the incision.

The values for the plasma proteins, preoperative and at the time of sacrifice of the animals for the control and experimental series are shown in Table II. In the control series, the average preoperative plasma pro-

Fig. 2. Control series, relationship of protein to mean wound tensile strength

tein for the whole group is 5.58 grams per 100 cubic centimeters, and at the time of sacrifice 5.44 grams per 100 cubic centimeters whereas in the experimental series the average pre-

operative plasma protein is 5.72 grams per 100 cubic centimeters, and the average protein value at the time of sacrifice was 5.25 grams per 100 cubic centimeters.

DISCUSSION

In the evaluation of the results when comparing control and experimental series of animals the effect of the factors known to influence wound healing must be considered. It has been repeatedly demonstrated that proteins and vitamin C influence wound healing; therefore, the adequacy of the control of these two factors must be considered in determining the effect of heparin on wound healing.

In this experiment the animals of both series received the same diet and were given excessive amounts of vitamin C parenterally. It was therefore believed that the vitamin C factor was not responsible for possible differences in wound healing between the control and experimental series.

The protein levels in the two series were not so readily controlled because of unmeasured and variable blood loss particularly in heparinized rabbits. In the control series there was an average plasma protein loss between the preoperative period and the time of sacrifice of 0.14 gram per 100 cubic centimeters. In the experimental series there was an average loss of 0.45 gram per 100 cubic centimeters. With the greater average loss of protein in the experimental group of animals, it is important to determine if there is any correlation between protein loss and wound strength in each series of animals. The effects of protein change on wound strength can be represented graphically by plotting wound strength deviation from the mean wound strength for each series of animals against the difference in preoperative and postoperative protein for each animal in the two series. In Figure 2 it is seen that in the control series there is no relationship between change in protein level and wound strength deviation from the mean, since the 18 animals having protein loss were equally divided as to wound strength above and below the mean. This same distribution above and below the mean is found in the animals showing a

gain in protein. In Figure 3 the relationship of the change in plasma protein to wound strength deviation from the mean is shown for each animal in the experimental series. Although a greater number of the animals in the series showed a loss in protein, 8 of them having a loss had wounds of tensile strength above the mean. Therefore, the changes in plasma protein in the control and experimental series did not influence the wound strength in either series to an appreciable degree.

The differences in wound strength found between the control and experimental series is not great, but one of statistical significance on analysis.

Although not statistically controlled the fact that in the experimental series as compared with the control series a larger proportion of stomachs ruptured at the wound instead of through the stomach wall tends to confirm the unfavorable effect of heparin on wound healing as demonstrated in the abdominal wounds.

CONCLUSIONS

1. In the heparinized series of rabbits, the wound strength, 6 to 14 days after operation is less than in the nonheparinized series. The difference is statistically significant.

2. Twice as many heparinized rabbits died postoperatively before the time of sacrifice as nonheparinized rabbits. This fact introduced a possible selective factor into the experiment.

PRESERVATION OF FUNCTION IN CYSTIC AND SCLEROTIC OVARIES

Report of Sixteen Cases of Single Ovary

PHILIP JACOBSON M.D., Petersburg Virginia

THE function of ovaries embarrassed by cystic and sclerotic disease need not be lost because of the inability to dispose of offending follicles. With a proper understanding of the pathology it is possible to explore these organs and preserve or perhaps even improve their utility. The statement has been made that since cystic follicles are generally distributed throughout the entire ovarian stroma, complete resection of the cysts is impossible without oophorectomy and furthermore would be ineffectual even if accomplished as it is obvious that the original trouble lies beyond the ovary (11). It would seem that if the original trouble was always outside the ovary when polycystic disease exists then both ovaries should be similarly affected, whereas actually one ovary is involved while the other remains clear just as often as both ovaries are attacked.

To prove clinically that such ovaries are amenable to surgical therapy I believed it necessary to demonstrate on single impaired ovaries that they were capable of resuscitation. Then there would be no question of controls or whether one ovary was carrying all the burden when two are present. The opportunity was presented by the overwhelming failure of surgeons to persevere with the many conservative gynecological measures like the extended myomectomy and cystectomy of Bonney (3) and Falk's tubal division for salpingitis which reduce to a minimum the need for removing any part of the internal genitalia, particularly in young women. But as this pernicious and mutilating practice continues unabated, I have taken advantage of it in those instances where one ovary has been left behind to deny that it is impossible to take away all the enlarged follicles without removing the ovary and to sustain the principle that when follicles

obstruct the circulation and innervation especially where these enter the organ the ovary may be given a new start and restored to usefulness after these hindrances are removed. This applies not only to ovaries enlarged by polycystic disease, but more especially to the apparently normal ovary which contains in distinct and inconspicuous threats to its function.

Although the operation has been done on 155 patients only 16 form the basis of this report. They are women who have only one ovary since both tubes and the other ovary had been removed, presumably for pelvic inflammatory disease. At intervals of 1 to 9 years this single remaining ovary became not only inadequate but also disabling forcing these patients to seek relief. Instead of removing the crippled organ an attempt was made to restore its dynamics so that complete castration with its attendant evils could be averted. Its success has surpassed my expectations, and since the therapeutic armamentarium including endocrine and psychiatric therapy was exhausted before surgery was suggested it is logical to presume that the operation was the sole reason for the results obtained and should be applicable with even more benefit when both ovaries are present. This procedure therefore is presented as an other aid in preventing the deplorable and contemptuous treatment of the female genitalia that is still so prevalent and to support the position that in the surgery of the ovary excision should be the last and certainly not the first resource for the gross irregularities so frequently encountered.

The results in the 139 patients with two ovaries have been worthwhile and will be the subject of another report. Of these, 36 were patients with previously diagnosed ovarian disease, while in the remainder the procedure

From The Surgical Section, Petersburg General Hospital.

was part of some other operation which required entering the pelvis. However with the exception of size the pathology differs in no way from that of the 16 cases of this report although in the latter the scars adhesions, and contractures of the previous operation increased the difficulty of the exploration and intensified the cortical fibrosis.

PATHOLOGY

Farre in addition to being the first to describe that important but neglected area of the ovary which he designated as the white line pointed out that an ovary which appears to be normal may indeed have one-third to one half of its volume occupied by what he termed morbid follicles. As he put it "The morbid follicle occurs as a single cyst in the midst of otherwise healthy tissues. Although occupying more than one-third of the entire ovary it scarcely disturbs the even outline of that organ. Its coats are of uniform thickness throughout. There is no attenuation or preparation for dehiscence at any particular spot nor external sign of increased vascularity in one point.

These follicles do not rupture nor do they regress rapidly and thus become an impediment in the mechanism of cyclic activity. But their consequence varies with position and if they happen to be placed near the mesovarian border beneath the thick unyielding cortex of the white line the circulation and innervation are obstructed right where these enter the ovary. The circulation is compressed not only between follicles and the cortex, but also between the follicles themselves thus preventing the formation of a collateral circulation.

This is no rare occurrence. It happened in every one of the 16 cases of this report and in 60 per cent of the ovaries of normal size in the remainder of the series. In fact only one ovary of the 16 was enlarged and that was by a hemorrhagic cyst. This frequency raises the question of whether the normal ovary can be recognized from a casual inspection of its exterior.

The ovary can of course be expanded by multiple cysts or multifollicular and single cysts so huge that the ovary becomes a mere appendage of the tumor. These are not con-

sidered in this discussion as this study is directed more at ovaries which are of normal size and configuration but whose function is impeded by difficulties it cannot overcome. The essential principles of ovarian exploration can be applied to these swollen ovaries with equal benefit and the ovary can be retained as a functioning unit.

Microscopic evidence of circulatory interference inside the ovary has been published elsewhere (9). As none of the ovaries of this series were removed I can add nothing to what already has been described. Continued study of the ovaries taken out by others confirms this picture.

Grossly while the follicles are clearly apparent, pathologists seldom see the true state of affairs. In the living person the line of demarcation at the hilum of the ovary where the vessels make their transition into it is distinctly defined since there is an abundant circulation in the mesovarium which contrasts sharply with that in the ovary below. Moreover there are often extensions of the disease in the mesovarium above which arise from follicle changes that mischance has brought to the ovary just below the white line. It is only by putting the mesovarium under tension while it is still in place that the presence of this scarring above the line can be used to locate a malevolent follicle below it. The intra-ovarian stresses disappear also when the ovary is disconnected from the circulation. What may seem to be a flaccid organ out of the body can have areas of increased pressure when within it that may really be the deranging forces.

These concealed tense follicles can be the source of ovarian pain even when there is no enlargement or evidence of adnexal disease. While this pain usually radiates to the thigh or sacroiliac region it may simulate the symptoms of appendicitis especially in teen-age girls. Failure to detect such follicles are the cause of numberless appendectomies which are succeeded by oophorectomy with its distressing sequelae. It is not unlikely that they play some part in certain cases of dysmenorrhea and intermenstrual discomfort. The favorable and sometimes dramatic results of exploring apparently normal and obviously abnormal ovaries has led me to this conclusion.

A follicle expanding in or near the region of the white line provokes a more intense fibrotic reaction of the cortex there than at the free ovarian border. Corpora albicantia are often found in this area but as pointed out by Allen, maturation of a follicle is not required for them to come into being. The fibrotic processes surrounding these bodies, however tend to contract the ovarian cortex toward them even more than around follicles. In the larger series I found on four occasions definite follicles between the folds of the mesovarium itself. These had the appearance of ovarian follicles but may have been derived from the par-oophoron. The displacement of vessels could be seen easily but as this was taking place in soft tissues it was having little effect on the circulation.

Thus at the white line which is the junction of the peritoneal endothelium with the ovarian epithelium and is literally the life line of the ovary there is greater prospect for adversity. Dissection of this part of the cortex from the stroma beneath is much more difficult than from any other part of the ovary as the two surfaces are held together by strong fibrotic bands through which vessels and nerves must pass. A follicle maturing between these surfaces has less freedom and at the same time excites a more intense cortical reaction here than anywhere else. Nor is this reaction limited to the outline of the follicle. It reaches down over the ovary and up into the mesovarium, in the meantime squeezing the vessels passing through it, not only by contracting but also by occupying the spaces assigned to the blood supply. This is manifested frequently by hypertrophy of the white line which seems to embrace the hilum with a strangling band. If the fibrotic infiltration has not advanced too far engorgement of the ovary will take place when this tight structure is released.

In ovaries enlarged by polycystic masses the white line, or for that matter, the remnant of the ovary itself is so hidden in the whole spread of that structure that it is hard to find. But the white line is quickly revealed if the suspensory ligament is traced down from the uterus as it will lead directly to this line and the ovary no matter how small or indistinct

that may be. The ovary will usually be found so compressed as to be practically useless yet it may contain many cells which while barely subsisting because of the compression are capable of being revived.

ETIOLOGY

The removal of one ovary is often justified by the fact that one testicle one kidney or even one lung will do the work of two if too great a burden is not put upon it. The difference in the character of physiological function is, however completely disregarded. Of all the endocrine glands the ovary is the only one which does not maintain the same physical unity continuously. Not only physiological changes of the hormones but variations of physical forces inside the ovary, caused by the incessant rise and decline of follicles, are constantly going on. One ovary is not adapted to the measured beat of the menstrual cycle that normally requires two. There is yet no proof that the ovaries alternate in ovulating but clinical experience provides enough signs and symptoms to indicate that they do. When one carries the burden alone cyclical rotations are taking place with such excessive rapidity that the ovary cannot accommodate them. Hence the ovarian stroma becomes enmeshed in a mass of follicles from which it cannot extricate itself, culminating finally in endocrine inadequacies and discomfort.

The endocrine aspect also must be considered in conjunction with the fluctuating forces inside the ovary. The decrease in total ovarian mass is followed eventually by a decline in the output of estrogen and progesterone which are essential not only for the systemic metabolism, but also for that of the ovary itself. When the demand for either cannot be met the basis for a vicious cycle is prepared since the two hormones reach their greatest magnitude at different times and the activity of one is largely dependent on that of the other.

With the remaining components of the menstrual cycle still operating the single ovary beset by internal physical difficulties and external endocrine stimuli cannot survive for long the struggle to perform its function. Nothing can be expected from endocrine

Figs. 3 to 4. Diagrams illustrating the mechanism of ascus occlusion at the ovarian hilum.

Fig. 3. Cross section of the normal ovary. Note that in the normal ovary the vessels are unhampered, that the maturing follicles are near the surface and that the circulation is able freely to traverse the hilum in both directions.

Fig. 4. A large follicle located right where the vessels enter the ovary. There is no indication on the surface of its presence and it could hardly be discovered by palpation. The vessels are caught between the enlarging follicle and the underlying tunica albuginea. It is doubtful if a collateral circulation can develop with sufficient rapidity to prevent damage to some of the ovarian stroma beneath.

therapy when the changes in the ovary have become firmly established.

There is little actual data on the percentage of women with only one ovary who eventually required the removal of the other, but there is plenty of evidence that this practice has been and still is severely condemned. Cassier reports that two-thirds of a series of women who have had one ovary removed eventually got into further difficulty with the remaining organ. If that statement be true then this series of cases represents only 24 previous operations. The 16 first operations were carried out by different surgeons who were working in as many localities.

Howard A. Kelly, commenting on oophorectomy remarked: "The surgeon must bear in mind that his relationship to his patient is

not dissolved with the successful performance of an operation—and he must decide if the remote sequelae of operative interference may be even more distressing to the patient than the present pains since she might become disabled in most relations of life. Proper surgery depends upon the recognition that what were once considered diseases of the tubes and ovaries are in many instances no diseases at all.

Arthur E. Hertzler was even more eloquent. He said:

"It has always been a mystery to me why surgeons should regard the castration of the human female with indifference even derision. Even now women come to the clinic in droves who have had ovaries removed and were wrecked by it. But fortunately the science of medicine constantly advances. Formerly it was the surgeons who castrated their patients; now it is the roentgenologists.

Fig. 3. Multiple small follicles in the ovarian hilum and a large unruptured one at the free border. These larger follicles which are usually emptied by just puncturing them may contain several smaller cysts any one of which can go on to occupy the space thus created. The smaller follicles in the hilum interfere with the circulation not only between the cyst wall and the cortex but also between the follicles themselves. Sometimes these extend along the whole length of the ovary between the white lines.

I will have no more of it. There is not a lesion in this chapter (Involutional States of the Ovary) which can be maintained as pathologic to a degree that justifies removal and none in which the removal of an ovary but makes the last state of the patient worse than the first. The difficulty is due to the attempts to solve problems by detached study. The pathologist describes what he sees, the surgeon in the simplicity of his faith in the infallibility of pathology accepts the symbols of speech literally and cuts. The microscope does not reveal function. The physiological phase of the ovary can be determined only by study of the living. The study of the patient before and after removal of the ovaries is the only way in which one can determine their relation to the well being of the patient. Some of the most intense reactions I have observed occurred in women who had their ovaries removed after the cessation of the menses.

Many more of equal eminence could be quoted, but as I stated little heed is given to

Fig. 4. A corpus albicans in the hilum. The reaction around these is greater than around follicles with clear fluid. Fibrous bands sometimes extending up into the mesovarium can be seen often with the naked eye and the cortex is firmly attached to it. Any combination of these conditions can be present and as there is little likelihood of either the follicles or corpora albicantia regressing in this strategic location, they more or less permanently alter the structural pattern of the ovarian stroma.

their admonitions. Although these men do not tell what happens to the remaining ovary when the other is taken away they imply that the remote effects are disastrous. The reason is that the single ovary becomes structurally incapable of carrying on continuously since it cannot cope with a pace that is too swift and a demand that is too great for its slow moving mechanisms.

The dynamics of ovulation are still obscure. Even though it is a process stimulated by an endocrine synchronism, physical forces play a large rôle in its execution, constantly changing the distribution of intraovarian pressures. The idea that during ovulation only one follicle enlarges is denied by Strassman. He stresses the point that several follicles around a focus expand but only one goes on to ovulate.

Fig. 6.

Fig. 7.

Figs. 5 to 7. Technique of ovarian exploration.

Fig. 5. An apparently normal ovary without any sign of trouble within it. However the transparency depicts its follicles and corpus albicans in the hilum with vessels caught between them.

Fig. 6. A short incision is made in either border not quite through the cortex just below the white line. The incision is completed with the end of the small knife while the blade is held parallel to the cortex. The flat of the blade sinks into the stroma separating it from the cortex and the knife is thus accurately placed between these two structures. The knife is then passed across the ovary to the

because a one sided proliferation of the theca interna of this follicle forms a cone directed

other border overcoming any resistance while the curved end is held against the cortex. A small incision is necessary sometimes to allow the knife to emerge because the ovarian capsule may be too tough for it to come through.

Fig. 7. An incision is made over the knife at the middle of the ovary and is then stretched by a small pointed clamp to open the mesovarium. The use of a knife here would cause too much bleeding. The point of the clamp is placed just beneath the peritoneum of the mesovarium which can then be incised with but little hemorrhage occurring. The cortex is opened along the length of the knife which is withdrawn.

toward the surface of the ovary. This cone, which is wedge-shaped on the cut surface in-

Fig 8

Fig 9

Fig 10

Fig 8 The white line is grasped with Allis clamps and the end of the tonsil knife used to dissect the cortex off the stroma. It should be separated into the mesovarium. If the dissection is done accurately there will be little bleeding. This part of the cortex may then be removed. Follicles which otherwise have escaped detection can easily be palpated with the forefinger. It is not difficult to distinguish a cyst from a corpus albicans. The former feel like soft balls, while the latter are harder and their outline is not as distinct. The corpora are not excised but merely broken up so the ovary can absorb them.

Fig 9. The middle cyst is enucleated. The stroma over

the follicle is separated and the cyst shelled out. Note the two smaller cysts behind it. Puncturing will suffice for these.

Fig 10. The largest follicle is enucleated. No harm is done if it does not come out intact but one must make sure there are no other follicles. Openings in the stroma should always be made from the mesovarium to the free border parallel with the vessels. There will be little bleeding. The cortex is sutured to the peritoneum of the mesovarium making a new white line and widening the mesovarium. If there is bleeding more sutures may be required but there is seldom need to completely close this opening. Fine cat gut on atraumatic needles should be used.

filtrates and penetrates the surrounding tissues thus making a path for the chosen follicle. The actual rupture after the follicle

reaches the surface of the ovary and protrudes beyond is caused by the cessation of proliferation of the theca cells while the membrane be-

Fig. The normal position of the uterus and its adnexa. Illustrations in textbooks convey the impression that the tube is below the ovary and the latter exposed to the peritoneal contents while all are spread out over the width of the pelvis. This sketch is presented to show the ideal location of the tubes and ovaries but of course this could not be attained in any case of this series because no tubes are present. This relation of the tube, ovary and broad ligament may account for the presence of adhesions to the ovary although raw surfaces due to ovulation are constantly being exposed. While this may not be the true reason, placing the structures in this relation after surgery of the ovary will prevent adhesions. The ovary should be pulled out of the cul-de-sac. This is usually accomplished by suspending the uterus according to the Baldy Webster method.

between the interior of the follicle and the peritoneal cavity becomes progressively thinner. Circulation on top of the vertex of the graafian follicle is interfered with by internal pressure and the capillaries do not contain blood cells inducing atrophy. The slowness of the process permits the rupture to take place in a very smooth manner.

When this action goes on near the ovarian cortex or along the free border little damage ensues if it is not completed. But when it takes place in situations that do not favor successful termination the ovary will now contain a static body which is not readily discernible yet can alter more or less permanently

the entire internal structural pattern. This can and much more frequently than is popularly realized does, happen without any enlargement whatsoever and with no indication on the surface of the ovary of the disturbed conditions beneath.

These locations are deep in the center of the ovary and high up in the hilum between the white lines. Here the accidents of nature and the elements of chance come into play. There is no way of predicting which group of follicles is to be selected for maturation and it is pure misfortune when an adversely circumstanced one is picked. Exploration of such ovaries in the living quickly brings the realization of the futility of hormone therapy and explains some of the failures of this type of treatment in cases in which it would seem to have every opportunity to succeed.

ABSTRACT OF A CASE

Since all the patients presented a similar syndrome it would be needlessly repetitious to describe each one in detail. They differed from each other only in the prominence of a symptom or a sign. All the 16 women were between the ages of 25 and 33 and had had the first operation when both tubes and one ovary were removed from 1 to 9 years previously. Fourteen were white and two were colored. The diagnosis presented no problem and in deed often was made by the patient herself.

A typical case history follows

Mrs. C. L. C., white age 33 years was operated upon 9 years ago when both tubes and the right ovary were removed. She remained perfectly well for 6 years and her menstrual cycle and psychodynamic state were normal. Then she noticed that she was becoming more irritable and irascible, there was a reduction in the duration and quantity of bleeding, the intervals between periods became shorter and dysmenorrhea which was often disabling, increased in severity. At times there would be a continuous spotting over a period of weeks. Occasionally she would have severe discomfort in her left side which apparently had no relation to her periods. Colitis became painful and her libido disappeared. Flashes had started during the previous year.

She was a tall, well developed, poorly nourished woman who lost her emotional control as she recited her history along with the fact that several doctors had informed her that the remaining female organs would have to be taken out. She had already received endocrine therapy. With the exception of the psychological disturbance no abnormalities were

found besides those pertaining to the genital tenderness, spasm and rebound tenderness in the left inguinal region were present but no masses were discovered. The cervix was slightly enlarged and the uterus was normal in size moderately retroverted and sensitive. While no actual tumors could be made out in the left adnexal region some thickening was noted and extreme tenderness was elicited with just moderate pressure.

At operation (January 8, 1945) the old midline scar was excised and the abdomen entered after many intestinal attachments were separated. Both tubes and the right ovary were absent and the pelvic peritoneum was thicker than normal. The left ovary was buried in a mass of adhesions and when released was found to be about 1½ inches in diameter and under severe internal pressure. A cyst at the free border was inadvertently opened and found to contain dark grumous material. Several other small follicles containing the same matter were around the larger one. The mesovarium which was on tension and partially twisted was freed and the circulation to the ovary exposed. The hilum and mesovarium were then opened and explored. Several small follicles, each about ¼ inch in diameter and one about ½ inch in diameter along with one corpus albicans were removed. These did not reveal themselves in any way along the surface of the ovary. To maintain the ovary in as favorable position as was possible under the circumstances and keep it out of the pelvis the round ligament was shortened and several reefing sutures were taken in the infundibular ligament. The abdomen was closed and the convalescence proceeded uneventfully.

She was discharged from the hospital in 10 days with instructions to return after the first period was over. She came in jubilant. The period lasted 4 days, was without pain and the flow was much greater and of normal color. In a few months she reported again. Her constant emotional tension had disappeared and premenstrual distress was comparatively mild. Her libido was regained, the flushes and irritability vanished and she increased to pounds in weight. In fact she presented an entirely different personality which seemed to emanate just as much from the disappearance of tension as from the relief of discomfort. She has continued to maintain this improvement up to the time this report was submitted for publication.

The others have been almost as fortunate although the result was not obtained so quickly. Relief from suffering restoration of the cycle and emotional adjustment eventually was obtained in every one. One has endured for 3 years but now has some menopausal symptoms at 34. Another began missing periods a year after operation but now the regularity has returned. Three could not be traced more than 6 months but the rest are without discomfort and are enthusiastic about the outcome.

TECHNIQUE OF OPERATION

Bonney an ardent advocate of conservatism states that "there is a pleasure pride and satisfaction in conservative operations which cannot be appreciated save by those who have performed them but it requires of the surgeon that he should forego a procedure which achieves a striking result in a startlingly short time for one which though it takes longer has far greater appeal to the connoisseur." (4) This certainly applies to ovarian exploration. Judging from the results of the whole series of cases sometimes disappointment and failure were converted to success only after several months had elapsed.

This operation is not the same as the ovarian cystectomy of Bonney the decortication procedure of Reycraft the splitting operation of Bailey or Stein's excision of a wedge at the ovarian border. None of these attack the impeding factors at their source in the ovarian hilum between the ventral and dorsal white lines and all are more or less empirical in their approach. While undoubtedly effective they fail to recognize the pathology that may exist in the narrow and vital area where vessels and nerves make their transition from the mesovarium to the ovary and provide no method for correcting it.

The first step in exploring the ovary is to examine the mesovarium observing particularly the number of vessels going to the ovary and the presence of varicosities. The latter are usually part of a general varicose condition of the broad ligament and when present must be taken care of first. Because of the previous operation the mesovarium of every ovary in this series was distorted by adhesions rotation or malposition and it required much manipulation to bring about the normal relationship again. Without previous surgery the mesovarium is usually clear. Restoration of a straight mesovarium without deformity and with the ovary properly suspended is of supreme importance. This is often difficult and requires much finesse when adhesions between the ovary and whatever happens to be covering it are divided.

The ovary is held by the fingers, as instruments may do damage because of the friability of the tissues. A clamp is not placed across the

mesovarium to prevent bleeding since cutting off the blood supply even for so short a time reduces the internal stresses in the ovary and prevents accurate observation of the state of the circulation. If the operation is done properly the loss of blood is negligible and I have not found it necessary to remove an ovary on that account though more than 300 have been explored.

After the mesovarium has been straightened and the position and thickness of the white line have been noted an incision about $\frac{3}{8}$ inch long is made into but not through the cortex parallel and close to either border just below the line. A flat double edge tonsil knife with a round sharp end is then used to separate the cortex from the stroma. With the knife held in the same plane as the surface of the ovary the end is placed in the incision and with a few short strokes the remainder of the cortex is cut through and the back of the knife sinks in to the ovary against the stroma. Thus the blade is accurately placed between the cortex and the stroma. Holding the curved sharp end firmly under the surface of the cortex the knife is passed across the ovary until the end can be felt near the opposite border when a small incision is made over it allowing the end to come through. It is not easy to pass the knife across the ovary. One will be amazed by the density and firmness of the tissues, but by using the twisting movement of an oyster shucker and unhesitatingly overcoming any resistance the cortex can be separated from its underlying stroma without injury to either.

Keeping the knife in that position an opening is made about the middle of the ovary right over the knife and a clamp is inserted into this opening pointing upward parallel to the vessels in order to spread this incision wide and dissect up under the white line and into the mesovarium just beneath its peritoneum. The cortex is then divided over the knife between the two end incisions and the knife is withdrawn. The hilum of the ovary is now exposed and the interior of the ovary is accessible. Unless bleeding is profuse which seldom happens no effort is made to stop it.

The edges of the open white line are grasped with Allis forceps and that part of the cortex is dissected upward and cut off. One must not

cut too close to the ovary as blood vessels which are close under it might be severed. The finger is inserted into this opening and the position of the cysts or corpora albicantia, which cannot be detected through the intact cortex can easily be discovered by palpation with the forefinger.

The latter are broken up with a pointed probe but follicles should be enucleated if possible. This may be done with the sharp round end of the knife. If one bears in mind that the trabeculae of the stroma run parallel from the mesovarium to the free border and works only in that direction there will be little bleeding and few ovarian cells destroyed. If it is not practicable to shell out the follicles they should be opened but the aperture must be made adequate and sufficient to scan the interior to detect smaller follicles within.

Careful inspection of the wall of a follicle will disclose why puncturing rarely suffices for their complete disposal. The majority are not single follicles but a nest of several with one large and a few smaller ones. Piercing the large one merely permits it to refill or else allows one of the smaller ones to expand and occupy the space. Frequently what appears to be one large follicle may be a cluster of several smaller ones of almost equal size which together present the appearance of a single well rounded cyst.

It is not imperative that these structures be taken out. There is no pathological condition at hand that can be considered a disease. The effort is directed at relieving obstruction and strangulation. That is why partial resection of an ovary is silly. The part left behind still contains the same impediments and the only change has been an unnecessary and certainly undesirable reduction in the total ovarian capacity.

When the exploration is completed the ovary may be reduced in volume and one will often find that what externally seemed to be an ovary of normal size and shape actually consisted of only $\frac{1}{3}$ stroma and the rest follicles of one kind or another. Hence to allow for possible expansion of the stroma the cortex should not be closed too tightly. Using fine catgut on atraumatic needles the lower border of the open cortex is joined to the open peritoneum.

of the mesovarium so the latter becomes a straight line along with that of the cortex, in effect a new white line is created. Two sutures placed close to the apex of the incision into the mesovarium are usually enough and no more are needed unless there is oozing. Clamps, forceps, large needles or catgut and coagulation are avoided to prevent scarring. With the closure completed the ovary is now replaced and sutured as nearly as possible to its normal position and well above the cul-de-sac. In this series that could not always be done, but without the scarring and distortion of a previous operation it can usually be accomplished.

ADVANTAGES OF OPERATION

This procedure is not intended for those who do not have the remainder of the cyclic endocrine factors intact. It is not a substitute for and does not provide follicle or pituitary stimulating hormones. Women who once have had the elements of periodicity and have suffered significant deviations are likely candidates. The ovary and endometrium should be considered in the light of final links closing the procession of events in the menstrual cycle. They play a major endocrine rôle too just as important as others, but are much more liable to misfortune. Re-establishment of the ovarian link is the major objective for which fortunately these organs are accessible.

Nor should the operation be suggested until all other measures have failed to bring about improvement. In these 16 cases there was little likelihood of that happening but treatment was attempted and was of no avail. When two ovaries are present the chance for a therapeutic result are, of course, much better.

Returning to the concept of the etiology and pathology I have depicted it would seem that this operation would be futile aside from its value for this clinical study, since with only one ovary present the same abnormality is likely to recur. Perhaps that is true but before the recurrence takes place the woman is that much further along toward the normal time for the menopause and her adjustment to it has made comparable progress. It has been my observation that the artificial menopause, when precipitated in young women

either surgically or roentgenologically, is much more severe with more intense reactions than when it takes place at the proper age. A gain of 3 or 4 years is valuable and the probability of disruptions of the psychodynamic state is much less and in direct proportion to the number of intervening years. Hence the closer the time of the artificial menopause approaches that for the normal climacteric the less likelihood there is for physical and mental upsets. These women readily accepted the idea of preserving whatever is left of their ovarian function and their continued enthusiasm over the outcome has not only been gratifying but signifies that their fervor is not the transient elation of convalescent patients. The results of ovarian inadequacy with its accompanying deprivation of estrogen is no light matter and is a constellation of emotion and feeling which the masculine mentality grasps only with the greatest difficulty if indeed he does at all. If only he would match his zeal for preserving ovaries with that which he has for retaining testicles there would be much less repressed and concealed misery as a result of his gynecological endeavors. Although synthetic and natural hormones are available which can be administered to imitate after a fashion the normal cyclical variations they are as yet only a poor substitute for those that are derived from within.

The popular surgical notion that the menopause when brought about prematurely reaches an end and takes place just that much earlier, is a cruel fallacy. The menopause does not terminate after having been artificially created until the natural span for that individual has elapsed. In the vast majority of such women who have come to my attention there are disagreeable sensations of discomfort at about the time the period usually takes place to say nothing of permanent alterations such as the gain in weight and the change in personality. The latter cannot be dismissed as merely an intensification of psychic factors already in operation. Only the most phlegmatic escape and then not entirely. Moreover at the normal time for the climacteric, after the patient has been tormented by these recurrent feelings perhaps over several years a new set of symptoms appears and endures for many

more months. These consist mainly of severe flushes, headaches, vertigo and emotional outbursts but one such patient who had an artificial menopause at the age of 35 at 49 developed severe depression hallucinations, agitation paranoia epistaxis, and dermatographia. The syndrome eventually was controlled by adequate estrogen and psychotherapy but for a while it seemed that sanatorium care would be required.

It is not generally recognized that excision of a tube may be the prelude to impairment of its ovary. Although it is thought the circulation is not injured there is no way of knowing because of the infinite variations just where and how the anastomosis between the ovarian and ovarian branch of the uterine artery which usually carries the largest volume of blood to the ovary is maintained. In addition after the tube is removed the ovary is drawn to the uterus by the sutures ligating the vessels of the broad ligament and thus the infundibular ligament containing the ovarian artery is put on tension. The creation of scar tissue and adhesions limiting the mobility of the ovary completes the picture.

And there is seldom need for removing a tube. Tubal disease even in the face of wide spread infection with purulent collections inside and outside the tube is not an indication for salpingectomy. On many occasions when the pelvic adnexa seemed to be one inflammatory mass I have uncovered the medial ends of the tubes evacuated their contents and divided and ligated them at that point. In addition it was necessary to maintain a stoma to prevent subsequent painful hydro-salpinx. So when the fimbriated end was closed another opening was made somewhere along the tube. This was still less hazardous and certainly not as shocking as taking out a tube from friable inflamed and bleeding tissues to which intestines usually were closely and sometimes inseparably adherent. Recovery has been so complete that little evidence of pelvic infection either functionally or by examination can be found. It seems that the whole pathological process just melted away like the redness, swelling and edema disappear around a healing furuncle. And it is just as illogical to excise these inflamed tissues

as cutting out the whole area of inflamed skin to heal a furuncle. Some of these cures have endured for 10 years. Even when the tube has been ruptured by an ectopic gestation it is necessary only to remove the latter divide the tube at its medial end to prevent recurrence and sew up the bleeding area to control the hemorrhage.

Similarly there are but few reasons why an ovary should be removed. Among these are of course cancer and gangrene caused by twisting of the pedicle. Possibly it may be best to remove an ovary that contains a cyst so enormous that there is little likelihood of retaining any functioning part. But there is no need to take out an ovary or even part of an ovary for nonproliferative retention cysts ovarian hematomas dermoids or an ovary that has been shriveled by a fibrotic process. Falk advocates removal of a circumscribed tubo-ovarian abscess but I have found even that unnecessary. Evacuation of the purulent material and division of the tube is all that is required. There is no way of predicting to what extent the ovary will regain its function after adventitious processes are no longer operating. Sometimes only a shell is left, but that part may contain enough cells to insure the continuance of function.

There is always the danger when exploring an ovary of uncovering a malignant or potentially malignant process and spreading it over the peritoneum. I have not encountered this yet and hence believe that while it is possible it is highly improbable.

Exploration of an ovary is not difficult and need not be reserved for only those cases where the diagnosis has been made before operation. I believe it should be part of every laparotomy where these organs can be reached. With prudence and proficiency there is little to lose and much to gain. It is a means for giving a fresh start to an ovary which may seem normal but yet is under the handicap of submerged follicles that give no indication of their presence on the surface. In these 16 cases there was no doubt of the diagnosis but their success was based on exploration of a much larger series of ovaries in the living and the concept of the pathology evolved out of the experience with them. A full apprehension

of this pathology often will be the means of retaining ovaries and restoring them to usefulness even in the face of extraordinary lesions which at first blush seem hopeless. But it does require that the surgeon pause and devote some time to the study of the pattern of each malformation whether it be large or small before attaching the fatal clamps. And he must also bear in mind that he has not only the surgical means at hand, but also postoperative endocrine and other therapy which should be more than ordinarily effective since there will be fewer unknown factors to be reckoned with.

SUMMARY

Ovaries can be encumbered by follicles which, while they may or may not cause enlargement, do interfere with proper hormone production and ovulation. This is especially true when such follicles develop in the hilum between the white lines just where the vessels and nerves enter the ovary. This is not a disease but rather a misfortune which can be corrected.

The opportunity to prove that these ovaries need not be removed has been furnished by the tendency of surgeons to disregard the many conservative gynecological measures designed to retain the internal genitalia especially those that are so important to the psychodynamic stability of the female. A technique for accurately, not empirically exploring the ovary is presented based upon a conception of the pathology that considers static follicles either large or small as the malefactor. In 16 patients from whom both

tubes and one ovary had been removed and the other had finally become inadequate this remaining ovary was explored with results that demonstrate these organs can be restored to usefulness at least for a time and need be wholly or partially excised only under exceptional circumstances. The success of the operation was demonstrated by the relief of discomfort, restoration of normal cyclicality and the return of emotional tranquility and personality adjustment. This procedure is presented as a conservative gynecological measure which can be applied to nonproliferative cysts of the ovary, the most common cause of ovarian failure.

But there is no need to take out an ovary or even part of an ovary for nonproliferative retention cysts, ovarian hematomas, dermoids or an ovary that has been shriveled by a fibrotic process. Falk advocates removal of a circumscribed tubo-ovarian abscess but I have found even that unnecessary. Evacuation of the purulent material and division of the tube is all that is required. There is no way of predicting to what extent the ovary will regain its function after adventitious processes are no longer operating. Sometimes only a shell is left but that part may contain enough cells to insure the continuance of function.

There is always the danger when exploring an ovary of uncovering a malignant or potentially malignant process and spreading it over the peritoneum. I have not encountered this yet and hence believe that while it is possible it is highly improbable.

Exploration of an ovary is not difficult and need not be reserved for only those cases where the diagnosis has been made before operation. I believe it should be part of every laparotomy where these organs can be reached. With prudence and proficiency there is little to lose and much to gain. It is a means for giving a fresh start to an ovary which may seem normal but yet is under the handicap of submerged follicles that give no indication of their presence on the surface. In these 16 cases there was no doubt of the diagnosis but their success was based on exploration of a much larger series of ovaries in the living and the concept of the pathology evolved out of the experience with them. A full apprehension

of this pathology often will be the means of retaining ovaries and restoring them to usefulness even in the face of extraordinary lesions which at first blush seem hopeless. But it does require that the surgeon pause and devote some time to the study of the pattern of each malformation whether it be large or small before attaching the fatal clamps. And he must also bear in mind that he has not only the surgical means at hand but also postoperative endocrine and other therapy which should be more than ordinarily effective since there will be fewer unknown factors to be reckoned with.

SUMMARY

Ovaries can be encumbered by follicles which, while they may or may not cause enlargement, do interfere with proper hormone production and ovulation. This is especially true when such follicles develop in the hilum between the white lines just where the vessels and nerves enter the ovary. This is not a disease, but rather a misfortune which can be corrected.

The opportunity to prove that these ovaries need not be removed has been furnished by the tendency of surgeons to disregard the many conservative gynecological measures designed to retain the internal genitalia, especially those that are so important to the psychodynamic stability of the female. A technique for accurately, not empirically, exploring the ovary is presented based upon a conception of the pathology that considers static follicles either large or small as the malefactor. In 16 patients from whom both

tubes and one ovary had been removed and the other had finally become inadequate, this remaining ovary was explored with results that demonstrate these organs can be restored to usefulness at least for a time, and need be wholly or partially excised only under exceptional circumstances. The success of the operation was demonstrated by the relief of discomfort, restoration of normal cyclicality and the return of emotional tranquility and personality adjustment. This procedure is presented as a conservative gynecological measure which can be applied to nonproliferative cysts of the ovary, the most common cause of ovarian failure.

THE TREATMENT OF EMPYEMA WITH TOPICAL AND SYSTEMIC PENICILLIN AND OTHER ANTIBACTERIAL AGENTS

An Analysis of Twenty Cases

W EMORY BURNETT M.D. F.A.C.S. GEORGE P. ROSEMOND M.D., F.A.C.S.
JOHN H. HALL, M.D. and H. TAYLOR CASWELL, M.D., Philadelphia, Pennsylvania

IN 1943 Drs. John Lockwood and William L. White representing the National Research Council allowed us the privilege of participating on a project directed by Dr. White to determine the value of penicillin in preventing empyema following lung resection. This complication was frequent in spite of refinements of technique and the administration of sulfonamides which had already greatly improved results. The remarkable protection afforded by administering penicillin systemically was soon proved on a small series of patients in whom resection had been done paired carefully with controls who received no chemotherapy of any sort. This work was published in 1944 (7). The complete protection of the treated patients compared with the routine occurrence of empyema in the controls led us to try topical treatment of empyema. We treated some spontaneous pneumococcal and staphylococcal empyemas with increasing success as we overcame the difficulties and improved the technique. With great trepidation we attacked a putrid empyema for which we had the profoundest respect. From sad experience we had come to classify this disease as a surgical emergency next in urgency only to asphyxia and hemorrhage. We removed as much foul pus as possible and reinstalled 25,000 units of penicillin in 25 cubic centimeters of saline. We were so imbued with the need for early surgery in such cases that we intended to institute drainage the following day if there was still a foul odor to the pus. However the following day there was much less pus; it was thinner and there was very slight residual odor. Of even more importance the patient's toxemia and fever were considerably reduced so that we continued

with this form of therapy to complete cure in 16 days. The first 4 cases were included in the report of Lockwood, White and Murphy (4).

At first aspirations were often inadequate in amount or frequency or both, and the doses of penicillin instilled were small. In a few instances culture became sterile quickly in spite of these errors and cure fortunately resulted in spite of the failure properly to apply the basic principles of the treatment of empyema by any method. These basic principles are simple but absolutely essential: (1) evacuation of the pus and (2) obliteration of the cavity. Any method which does not accomplish these ends is a failure. The few reports in the literature of aspiration treatment of empyema before the advent of penicillin indicated a great increase in morbidity and a definite increase in mortality by this method along with the frequent development of chronic empyema and of recurrences. However good though not perfect results can be obtained by the method of adequate aspiration with reinstallation of penicillin pursued vigorously by one thoroughly acquainted with the surgical principles involved. Secondary but very desirable considerations are sterilization of the infected space and re-establishment of pulmonary function which is accomplished only by re-expansion of the collapsed lung and pulmonary exercises. Resort to thoracoplasty is admission of partial failure. The method to be outlined can usually establish the required basic principles and the secondary considerations and can often greatly decrease the period of morbidity. It is essential for routine success that this method be used only by those whose extensive experience with the surgical treatment of empyema has taught them the

vagaries and elusiveness of pus in the pleura and the rapidity with which the lung can safely be re-expanded. Only such persons can recognize failure early and apply proper surgical drainage to accomplish cure and avoid serious complications.

RESULTS

Twenty patients with empyema were treated by aspirating the pus as completely as possible and instilling penicillin alone or with other agents into the cavity. Sixteen of these were cured by this method and 4 required surgical drainage. The ages ranged from 6 to 64 years, the empyemas were loculated in 18 instances and diffuse in 2 and the capacity the amount of pus extracted at one tap ranged from 18 cubic centimeters as a minimum to 1200 cubic centimeters maximum. Six were pneumococcal infections, 4 in pure culture, 1 associated with spirochetes and the other with nonhemolytic streptococcus and *Hemophilus influenzae*; the latter was one of the failures. Nine others were streptococcal, 4 of them pure cultures of nonhemolytic streptococcus by aerobic and anaerobic culture, two nonhemolytic combined with hemolytic streptococcus, one each of nonhemolytic streptococcus with bacteroids or diphtheroids and one was pure culture of hemolytic streptococcus. In 1 case only hemolytic *Staphylococcus aureus* was noted. One was a combination of *Hemophilus influenzae*, diphtheroids and bacteroids, and was another therapeutic failure. The 3 others revealed no growth; however the fluid was purulent grossly and cytologically and in 1 case smelled putrid. In 8 cases, the pus was putrid at the first aspiration. The average time of treatment excluding Case 20 was 14 days with the longest time 33 days and the shortest only 1 day. The average number of aspirations for the 20 cases was 7.7 and varied from 1 to 18. The average dose of penicillin initially instilled into the cavity was 63,250 units. Seven of the cured patients received no penicillin systemically, although 3 of them had a continuation of sulfonamide therapy by mouth. In fact one patient had been treated for 9 weeks before admission by repeated aspirations and the systemic administration of penicillin, without success. In 9 successful and all 4 unsuccessful

cases patients received systemic penicillin, ranging from 100,000 to 300,000 units per day and averaging about 200,000 units divided into 12 equal 2 hourly doses administered intramuscularly. The pus became sterile after a single aspiration and reinstallation on 7 occasions, after 2 such maneuvers in 2 cases and was not noted in 1 other. Penicillin was not instilled on every aspiration in some of the earlier cases, and taps toward the end of treatment were unsuccessful at times. Bronchial fistula was proved in 8 of these 16 patients and healed without further specific treatment in all. In no case was the fistula a very large one which might defeat such method. A few of these 16 patients had been ill for several months up to 1 year (Table I).

Of the 4 patients who required further treatment one showed *Hemophilus influenzae* which was not susceptible to penicillin; in 2 there were multiple loculations and the fourth was somewhat slow in improving, so was submitted to surgical drainage. These patients made a routine recovery after drainage except for the one with *Hemophilus influenzae* in whom two instillations of streptomycin preceding drainage abolished the positive *Hemophilus* cultures but failed to improve the patient's condition. Her recovery even after surgical drainage was extremely slow and the cause for this was never thoroughly explained in spite of repeated roentgenograms, bronchoscopies, cultures of sputum, bronchial secretions of the empyema cavity, of the blood and urine and vigorous supportive treatment.

No chronic empyemas resulted in the 16 successful cases and pleural thickening which was quite marked in some at the beginning disappeared completely as shown by roentgen ray and demonstrated in some of the examples depicted in this article. However there were 2 cases in which there was persistent pleural thickening; in one biopsy was done as it was feared that a tumor might underlie the empyema. These patients have been followed for from 6 months to 3 years after discharge without further evidence of disease or symptomaticology.

TECHNIQUE

1. Under adequate local anesthesia locate a favorable site near the bottom of the cavity,

TABLE I.—SUMMARY OF CASES

with a No. 20 gauge needle. Then insert a No. 14 or No. 15 gauge needle and use a 30 cubic centimeter syringe with a two-way stopcock as the best means of aspirating the fluid. If the pus is thin use a modified aspirator devoid of the little Potain valves which are useless and are often completely stuck or partially blocked by rust or cooked exudate. It is important to aspirate all the pus possible do not be satisfied with less than appears to be present from the physical signs and roentgenograms. It is usually impossible to get all of the pus since some is present below the level of the needle; this pus can be diluted and largely evacuated by lavaging with normal saline or azochloramide in a 3,300 aqueous solution. In the presence of thick pus which taxes one's ingenuity particularly if there are fibrinous clots with movement or rotation of the needle during release of suction reinsert a few cubic centimeters to blow out fibrinous material lavage and instill azochloramide; this procedure usually overcomes this difficulty. The adequate removal of thick pus is one of the greatest difficulties with this method. For the first 3 or 4 days maintain separation of pleural surfaces by pneumothorax or by volume of fluid reinserted to allow sterilization and to avoid development of multiple loculation if not already present.

2. When the cavity is emptied as thoroughly as possible instill 100,000 units of penicillin, 1 gram of streptomycin or 2 to 4 grams of sulfonamide alone or combined depending on susceptibility tests in appropriate amount of saline usually 25 to 50 cubic centimeters plus additional air if the capacity of the cavity is above 100 cubic centimeters to maintain separation of the walls.

3. Determine that the organism is susceptible to one of the available agents but continue the treatment until this is determined. If the bacteria are not susceptible to one of the agents available surgical drainage should be instituted without further delay.

4. Repeat procedure daily until cultures are sterile or nonsusceptibility is established.

5. As soon as cultures are sterile obliterate the space as rapidly as possible removing all liquid and gas but continue to instill 50,000 to 100,000 units of penicillin or appropriate

amounts of other agents in small volume as low as 1 cubic centimeter with each aspiration. Aspiration is continued every other day until no more fluid can be obtained and frequent roentgen ray check up reveals no further evidence of pleural cavity when taps may be discontinued.

6. Check up by roentgen ray in 2 weeks and again in 4 weeks using exploratory aspiration if roentgenogram indicates suspicion of persisting fluid or cavity.

7. Give the appropriate antibiotic (or chemotherapeutic agent) systemically. Penicillin is administered in 12 doses intramuscularly 2 hours apart totaling 240,000 units per day or more starting this at the beginning of the topical application. Streptomycin is given in similar fashion totaling 3,000,000 units per day. Sulfonamides are better given by mouth in the usual way.

8. If it is impossible to empty the cavity if susceptibility cannot be established or if satisfactory technique fails to relieve the condition within 10 to 14 days institute drainage.

PREVIOUS REPORTS

It is notable that the literature on this method is mostly adverse. A critical analysis however reveals that many of the reports are of small groups that patients have been tapped irregularly and infrequently that pus has been allowed to remain in the pleura even though sterilized or that surgical drainage has been instituted at once because of thick pus or the presence of bronchopleural fistula. Consider the article by that excellent surgeon Brian Blades in collaboration with Hamilton and Dugan in which they report 4 cases in which patients were treated at various Army posts. Of these the record indicates that dosage was inadequate in amount or time or both in 9 and that sterile fluid which might have been removed was present in 7, a total of 16 which might have been successful. In only 3 patients were nonsusceptible organisms present and in 3 others there was cure without operation. They note that pus became thicker as time went on although we have observed the opposite in our cases in that the pus becomes thinner from the first tap provided adequate removal is obtained. The reference to thick

pus and the inefficacy of this method occur in other reports including those of Roberts, Tubbs and Bates from England and Poppe who also feel that bronchopleural fistula is a contraindication. Poppe reports a recurrence rate of 53 per cent and quoted Butler Perry and Valentine as having a 28 per cent recurrence rate. He feels that treatment in this fashion greatly prolongs morbidity and that this is another reason it is not justified. We have seen no recurrences with the technique described above and have noted a great reduction in morbidity. He also feels that pleural thickening is more frequent and more crippling with aspiration therapy than with drainage. Prolonged thickening was noted in only two of our aspiration cases and has been present in most of our previous drainage cases as well. The thickness appears to be the response to infection and occurs in proportion to the virulence and duration and has been as routinely present in previous patients treated by surgery alone. Follow up roentgenograms of our patients showed routine disappearance of pleural thickening within a few months in all but the 2 mentioned.

On the other hand Lockwood White and Murphy reported 34 cases of pneumococcus empyema of which 19 were cured in this way with only 10 000 to 25 000 units of penicillin topically. One of these showed *Staphylococcus aureus* *Streptococcus hemolyticus* and pneumococcus. Hirschfeld Buggs Abbott and Pilling seem to have a most rational approach and although they do not state the number treated and the percentage of success they cite successful and unsuccessful cases and they as well as we emphasize the need for maintaining the principles of treatment of empyema with this method as with any other. Brown and associates, in reporting 24 cases of their own and 236 compiled from the literature state that in 144 patients treated with penicillin locally or systemically or both 92.3 per cent were cured, 2.6 per cent became chronic and 5.1 per cent died. In 104 patients treated by penicillin and surgery 90 per cent were cured, 3.8 per cent became chronic and 5.8 per cent died. They too call attention to the small number of injections in many cases, often only one or two injections being given

and frequently doses as low as 10 000 units being used.

Much of the criticism of this method may stem from analyses and compilations of cases in which patients were treated by physicians not surgically trained although certainly some of it represents poor results in the hands of good surgeons.

CONTRAINDICATIONS

It is quite probable that in certain cases with pus which is too thick for evacuation by large needle and persistent effort with organisms which are not susceptible or with the presence of large bronchopleural fistula which prevents proper lavage or retention of the antibiotic in the cavity, surgery would be necessary but these should be infrequent. The contraindications as they appear to us are:

- 1 Inability to evacuate the cavity
- 2 Nonsusceptible organisms
- 3 Inability to maintain antibiotic fluid in the cavity as in large bronchopleural fistulas.
- 4 Multiple loculi although theoretically even this might be overcome by tapping each loculus such tapping generally would not be feasible
- 5 Recurrence

CASE REPORTS

CASE 1: M S female, age 47 was admitted to the hospital January 2 1944 discharged February 4 1944. Diagnosis empyema diffuse right pneumococcus, postpneumonic.

This patient's illness dates from December 25 1943. She developed cough fever and labored breathing and was treated at home as pneumonia. The cough became more severe and productive and she was referred to the hospital. She presented signs of fluid over the right lower chest posteriorly her temperature was 102.2 degrees and she appeared quite toxic. The roentgen ray examination January 3 1944 revealed a large pleural collection within the right chest with displacement of the mediastinum to the left. February 11 1944 the roentgenogram revealed complete obliteration of the empyema cavity.

The patient was tapped on January 3 1944 and 900 cubic centimeters of greenish yellow fluid were removed. She was started on sulfonamides systemically. No penicillin was instilled on the first tap. After surgical consultation on January 13 1944 taps were done almost daily on January 14, 16, 17, 18, 19, 20, 22 and 29 10,000 units of penicillin being instilled at each tap. At the time of the last tap the size of the cavity was approximately 35 cubic centi-

Fig. 2. Case 1, A.R., female, age 40. Left, empyema on left demonstrated 1 day after admission. Right, 10 days after admission.

patient had a 10- to 15-cc sanguinolent fluid with 100,000 to 200,000 cells were found in the specimens. On January 16, 1944, following this on three (3) specimens gram positive diplococci were seen on smears, but there was no growth. Following these (3) specimens the fluid was sterile and showed no organisms. The patient received no systemic penicillin. Her total fluid intakes consisted of 6 grams per day. Her weight was 21 lb. in 1944, inclusive none being given during empyema treatment.

(4) The most recent examination of this patient on December 12, 1946. She had had no further cough, dyspnea or other respiratory symptoms and had gained 118 pounds in weight. There is no recurrent thickening on roentgenogram.

(Case 2) A.R. female, age 40, was admitted to the hospital January 10, 1944, discharged February 29, 1944. The gross empyema massive left pneumococcus.

Fig. 3. Case 3, A.R., February 25, 1944, approximately 7 weeks after admission and 3 weeks after last successful tap. Marked pleural thickening and the usual blunting up of diaphragm after empyema treated by any method appear, but no cavity is demonstrable.

Fig. 4. Case 3, A.R., on March 30, 1944, 1 week after admission and 8 weeks after last successful tap. Pleural thickening greatly reduced. Diaphragm still elevated.

Cough, fever, weakness and toxemia for the 3 weeks prior to admission beginning insidiously with an upper respiratory infection. Patient presented a marked pallor with signs of fluid in left chest and cervical adenopathy. On January 10, 1944, roentgenogram revealed massive left pleural effusion with the condition of the underlying lung indeterminate.

The patient was first tapped on January 11, 1944, and thick pus culturing pneumococcus, type 3 was revealed. Beginning on January 13, 1944, or 4 days after admission aspirations were done daily with reinstitution of 12,500 units of penicillin. Aspirations were rather small, ranging from 1 1/2 to 90 cubic centimeters, and cultures continued to be positive. On January 19, 1944, a determined effort removed 360 cubic centimeters, and from this point on progress was rapid. Cultures became sterile from January 24, 1944, and for subsequent studies, and only small amounts of bloody serous fluid could be obtained thereafter. From this point on her temperature rapidly returned to normal and she improved clinically. The last successful thoracentesis was February 3, 1944, approximately 10 days after the thorough aspiration and only a few cubic centimeters of serous fluid were removed. On discharge the patient showed complete obliteration of the empyema cavity with some residual pleural thickening. She was asymptomatic, her leucocytosis had disappeared, her sedimentation rate was normal, and physical signs in the chest were practically normal.

Follow-up. The patient was seen up to 34 months after discharge, and both clinical and roentgen-ray examinations were entirely normal (see Figs. 1 to 4).

(Case 3) A.S. male, age 55, was admitted to the hospital March 10, 1944, discharged April 12, 1944. Diagnosis (1) empyema loculated left (2) fistula bronchopleural (3) abscess subcutaneous.

Five months before admission, a diagnosis of left-sided pleurisy and pneumonia had been made. Since this acute episode the patient had improved but had

Fig. 4. Case 2. A. R. on November 12, 1946, 35 months after treatment showing normal lung fields and pleura. Diaphragm has returned to normal position and activity.

never felt well and had continued to have pain in his left chest with some dyspnea and a persistent productive cough. The cough became worse when he lay on his right side and the sputum was profuse but not foul. He had lost some 10 pounds in weight. In the last 2 weeks he had noted a hard red swelling over the left chest wall anteriorly which had increased in size but had not drained. Examination disclosed enlarged left suprascapular nodes, lagging and dullness over the entire left chest with suppression of breath and voice sounds. In the anterior axillary line at the sixth rib there was a red, tender mass about 5 centimeters in diameter which was attached to underlying muscles and costal cage. Roentgenograms revealed a hydropneumothorax on the left which was located in the lower lateral portion from the diaphragm to the third rib. There was some infiltration of the left lower lobe suggesting pneumonia, and accentuation of the lung markings in the right lower lobe suggesting possible bronchiectasis.

Aspiration on March 11, 1944, 2 days after admission obtained 210 cubic centimeters of bloody thick, putrid pus which on culture grew pneumococcus and spirochetes. The red mass was drained and found to be a local abscess not communicating with the pleura which showed a hemolytic *Staphylococcus aureus*. Aspirations were done on March 12, 13, 14, 15 and 17 at which times penicillin 50,000 units was instilled except on the 15th when an unsuccessful tap was encountered. Pus on March 12, 1944 was nonodorous and that obtained on March 13, 1944 was sterile. There was no other positive culture on any subsequent tap. On March 24, 1944 roentgenogram showed a reaccumulation of fluid and he was aspirated on this date and on March 25 but on March 27 and March 29 the taps were unsuccessful. How-

ever they were again successful on April 1, 5, 6, 8, 10 and 12. On the last tap only 5 cubic centimeters of thin, very slightly bloody fluid were removed. Penicillin was given intramuscularly from March 10 to 18, 1944 at the rate of 150,000 units per day. He was discharged on April 12, 1944 with a healed wound at the site of the drained abscess and without respiratory symptoms. Roentgenogram showed obliteration of the pleural cavity but continued to show a localized area of pleural thickening. This continued without much change for 6 weeks which increased our fear of an underlying tumor which had been suggested by the bloody fluid. For this reason a biopsy of the pleura was done on May 29, 1944 but only chronic pleuritis was found.

Follow up. On September 24, 1945 approximately 17 months after discharge, the patient had remained free of cough, expectoration and fever, and roentgenogram revealed only slight residual pleural thickening with blunting of the left costophrenic sulcus and elevation of the diaphragm.

CASE 4. B. B. female age 26 was admitted to hospital May 29, 1944 discharged July 5, 1944. Diagnosis: (1) bronchiectasis right lower lobe (2) empyema loculated right putrid postlobectomy (3) fistula, bronchopleural.

Bronchiectasis followed the inhalation of grass head at the age of 9 years. Cough and expectoration had been present since and hemoptysis and malodorous sputum were recently noted. Examination revealed dullness of right base otherwise negative. Roentgenogram June 9, 1944 (first postoperative x-ray) showed fluid present along the right lateral chest wall and a fluid level of the fifth interspace in the posterior axillary line. June 24, 1944 the roentgen ray appearance of the chest improved considerably in the past 11 days resulting in disappear-

Fig. 5. Case 6. R. O. on January 30, 1945, fluid posteriorly and laterally following right lower lobe pneumonia.

Fig. 6. Case 6. R. O. 8 days after last successful thoracentesis.

ance of fluid loculation in the posteromedial aspect of the chest. Undrained fluid collections were evident.

Following lobectomy on June 5, 1944, for right lower lobe bronchiectasis done without chemotherapeutic protection, the temperature remained elevated and roentgenograms showed pockets of fluid. On June 13, 1944, thoracentesis was done and 150 cubic centimeters of bloody, foul-smelling fluid were removed and 20,000 units of penicillin instilled. Culture of this material showed *Bacillus pyocyaneus*, many nonhemolytic streptococci and a few bacilli. On June 15, 1944, another tap was done, 150 cubic centimeters of very slightly odorous fluid were removed and 20,000 units of penicillin instilled. Culture was again positive. No subsequent cultures could be obtained. On June 17, 1944, the procedure was repeated, large amounts of air removed and 20,000 units of penicillin instilled. On June 20, 1944, thoracentesis was again done but no penicillin instilled. On June 21, 1944, thoracentesis was done, removing much air but no fluid and 20,000 units of penicillin were instilled. On June 24, 1944, 20,000 units of penicillin were instilled. Air was still present at this time. No other thoracenteses were done. On July 5, 1944, the patient was discharged with a normal temperature. At that time there was practically no sputum. Morbidity after operation had continued with a temperature of from 101 to 103 degrees until the tenth postoperative day when the second thoracentesis was done. The temperature then dropped rapidly to normal and remained so until discharge. No sulfonamides were given.

Follow-up. Following discharge the patient received weekly instillations of penicillin by bronchoscope because of a bronchial fistula and fear of re-contamination; however dosage was not noted. On September 28, 1944, she was seen by us and was absolutely asymptomatic. Roentgenograms taken in Texas in November, 1945, showed no residual cavity or pleural thickening. Two communications received from the patient's family physician 2 years following the procedure stated that she was com-

pletely asymptomatic and roentgenograms of the chest were entirely negative.

CASE 5. E. D., male, age 29, was admitted to the hospital November 20, 1944, discharged January 18, 1945. Diagnosis: (1) pulmonary suppuration, bilateral, diffuse; (2) empyema, loculated, left.

In 1943, the patient had 13 teeth extracted, following which he developed fever, productive cough, nausea, vomiting, and 3 days later he coughed up a portion of a tooth. He developed 5 attacks of pneumonia since this episode, of which 3 were in 1944. He was given a course of sulfonamides on the outside with no relief. He had marked dyspnea and pain in the left lower chest. Examination revealed dullness to percussion posteriorly over both bases extending up to sixth thoracic. Coarse rales were heard over both bases, and breath sounds were diminished. There were tachycardia, fever and weight loss. Roentgenograms November 21, 1944, revealed widely disseminated disease in the lungs, probably nontuberculous in character. December 1, 1944, the chest appearance was somewhat worse than on examination 10 days ago. There was an abnormal density in the left lung which had increased in extent and showed confluence. There was fluid collection in the left base. January 1, 1945, marked improvement was noted with only pleural thickening present. No empyema pocket was found.

Systemic penicillin, 100,000 units, was given intramuscularly from November 24 to December 16, 1944, with little improvement. All sputum specimens were negative for tuberculosis. On January 4, 1945, surgical consultation was requested, and a diagnostic left thoracentesis obtained 5 cubic centimeters of foul greenish pus which grew many hemolytic streptococci. On January 5, 1945, a therapeutic tap removed 350 cubic centimeters of similar pus. The cavity was lavaged with saline and 25,000 units of penicillin in 50 cubic centimeters of saline was instilled. The pus showed the same organisms, but all subsequent cultures were sterile. Thoracenteses were repeated on January 6, 8, 10, and 12, obtaining 90, 40, 25 and 10 cubic centimeters of nonodorous fluid.

which became thinner until the last 10 cubic centimeters appeared to be a solution of penicillin in consistency and color. On each occasion 25,000 units of penicillin were reinstalled. From January 10, 1945, the patient felt much better, gained weight and was free of his distressing cough. His low grade fever disappeared permanently after the first instillation of antibiotic. He was discharged on January 18, 1945, markedly improved clinically and roentgenograms showed similar improvement in the parenchymal disease on the left and in the pleural disease.

Follow-up. Subsequent roentgenograms continued to show bilateral pulmonary disease. The patient was readmitted in November, 1946, with evidence of right sided pleural thickening and parenchymal fibrosis. However, the left pleural space remained entirely free of infection and has continued so to the present. A right lower lobe lobectomy was performed with resection of a portion of the diaphragm, liver and parietal pleura for his right sided pulmonary, pleural and hepatic disease which resembled actinomycosis but was not proved microscopically.

CASE 6. R. O. male age 6 was admitted to the hospital January 21, 1945, discharged March 11, 1945. Diagnosis: (1) pneumonia, right lower lobe; (2) empyema, loculated right, streptococcal.

Fever and cough were present for the 2 weeks prior to admission. He was treated with sulfonamides by his local doctor with no improvement. He was admitted with a diagnosis of right lower lobe pneumonia. Examination revealed an increased respiratory rate and dullness to percussion posteriorly in the regions of the right middle and lower lobes. Breath and voice sounds were diminished. An occasional moist rale was heard over the right base. Roentgenogram January 22, 1945, revealed consolidation of the right middle and lower lobes, interpreted as pneumonia. There was a question of fluid in the right pleural space. January 30, 1945, pneumonia had resolved. There was appreciable fluid collection in the right pleural space which appeared to be loculated. March 10, 1945, roentgenogram showed no evidence of pleural disease.

The patient was placed on sulfonamides on admission with immediate improvement. A dosage of 3 grams daily was given from January 21, 1945, to February 10, 1945. His temperature returned to normal the third day after admission. One week after evident resolution of pneumonia, the patient developed signs of fluid in the right chest and temperature elevation. A diagnosis of empyema was made. Thoracenteses were done on January 20, 30, and 31, and February 3. The initial tap produced 18 cubic centimeters. Bacteriological examination revealed an anaerobic, nonhemolytic streptococcus on January 20, 1945. Thereafter all fluid was sterile. The first three thoracenteses were productive. At the last tap no fluid could be obtained. Penicillin 30,000 units was instilled at each tap. He was begun on 100,000 units of penicillin intramuscularly daily on January 30, 1945, which was continued until February 21, 1945.

Fig. 7. Case 6. R. O. 19 months after treatment. Entirely well.

Follow-up. Since discharge the patient has had no recurrence of chest symptoms. He was seen in August, 1946, at which time he had no pulmonary complaints. Examination of the chest was entirely negative and check-up roentgenograms showed no pathologic change and no evidence of pleural disease.

CASE 7. A. P. female age 43 was admitted to hospital January 31, 1945, discharged April 25, 1945. Diagnosis: (1) bronchiectasis; (2) empyema, posterior left; (3) fistula bronchopleural.

The patient had a left lower lobectomy 6 months prior to this admission. She had a known bilateral bronchiectasis and a history of asthma. On January 20, 1945, she noted upper respiratory infection with chills, fever and pain in the left lower chest and abdomen. A productive cough began on the date of admission. Examination revealed an acutely ill woman. Her respirations were 36, pulse 144, and temperature 103 degrees. There was a lag in the left chest with dullness at the left base posteriorly and signs of fluid in this region. Roentgenogram February 1, 1945, revealed a large hydropneumothorax in the left chest with a broad fluid level. The left upper lobe was collapsed. April 10, 1945, roentgenogram revealed thickened pleura in the left chest, but no air or fluid pocket.

On admission the patient was markedly debilitated and showed a morbidity which persisted throughout her hospital stay. Her temperature spiked as high as 102 to 103 degrees daily. The first two taps showed no purulent material and revealed no organisms. The first measurable amount of fluid was obtained on February 1, 1945, when 10 to 15 cubic centimeters were removed with large amounts of air. Culture on this material was sterile. The tap was repeated on February 8, 1945, but no fluid was obtained. On February 19, 1945, 60 cubic centimeters of malodorous pus were withdrawn and 16,000 units of penicillin instilled. Bacteriological examination revealed pneumococci type 5. On February 21, 1945, 100 cubic centimeters of odorous pus were removed and 20,000 units of penicillin instilled. On February 23, 1945, 180 cubic centimeters of thick

Fig. 8. Case 6. H. R., on June 6, 1945 admission films showing loculated empyema, right base posteriorly

brown nonodoriferous fluid were removed and 20,000 units of penicillin instilled. Failure to respond to this sporadic treatment and the scarcity of penicillin made us elect surgery. On February 26, 1945, the cavity was opened and drained. The empyema fluid never became sterile on the infrequent penicillin instillations. The left upper lobe remained atelectatic until controlled drainage with suction was placed in the left pleural space. On April 11, 1945, a small cavity near the apex was discovered and this was tapped on April 12 and 13, 20,000 units of penicillin being instilled each time. The material obtained from this pocket was sterile. The underlying lung disease probably played a large factor in this patient's continued morbidity, and she was discharged at her own insistence running a moderately septic temperature.

Follow up. The patient was seen again in June, 1945, on a readmission at which time she showed marked debility and edema due to protein deficiency. Roentgenogram at this time showed a fluid level in a new location in the apical portion of the left chest which was definitely localized in the pleural space. There was marked parenchymal adjacent lung disease. The patient was also still draining through the drainage opening in the fifth left rib bed made on the previous admission. She has been seen since in the out-patient department and continues to get along with difficulty, having dyspnea and a thymatic symptoms, although less than before lobectomy and slight drainage through the thoracostomy wound.

This patient was subjected to lobectomy originally after considerable thought and discussion in the chest conference. The bronchiectatic left lower lobe was removed in the belief that her severe asthma was produced by bacterial allergy from the bronchiectatic focus. She was improved and although she still has asthma it is much less severe.

Infection in the pleura was produced by a respiratory infection 6 months following lobectomy. There was difficulty in locating the pus. There were multiple pockets, the pus was malodorous, although only pneumococci could be grown from one of the pockets, and penicillin was scarce. She was therefore drained 27 days after admission and this, too, was not very satisfactory although adequate access was obtained by rib resection. She refuses additional surgery and we agree with her.

CASE 8. A. S. male age 35, was admitted to the hospital February 27, 1945, discharged March 17, 1945. Diagnosis empyema loculated right, pneumococci postpneumonic.

The patient was well until January 1945 when he developed what was diagnosed as lobar pneumonia on the right. He was treated with sulfonamides at home and his fever disappeared. A few weeks later he noted a temperature elevation each afternoon. He lost 34 pounds. Two weeks before admission he developed diarrhea, pain in the right chest, a productive cough and dyspnea. Examination revealed flatness at the right base posteriorly. Crackling rales were heard at both bases posteriorly. Breath and voice sounds were diminished on the right. There was slight abdominal distention. Roentgenogram February 28, 1945, revealed 2 fluid loculations in the right lower portion of the right pleural space, one lateral and one posterior. There was abnormal stringy density present in the left lower lobe. Roentgenogram March 12, 1945, showed that no significant change had occurred during the past week. At the time of discharge x-ray examination showed only a small residual cavity in the right lower pleural space.

The first tap was done on March 5, 1945, and 20 cubic centimeters of frank, nonodoriferous pus were re-

Fig. 9. Case 10. H. R., on June 18, 1945 after 12 days treatment showing multilocular cavity. Still had positive cultures. Drainage instituted the following day.

moved and 25,000 units of penicillin were instilled. The pus was cultured and showed pneumococci, type 5. Patient's temperature immediately returned to normal and his clinical improvement was dramatic. No other taps were successful in obtaining air or fluid. The patient received no systemic sulfa therapy. He received systemic penicillin from March 2, 1945 to March 17, 1945, 100,000 units daily.

Follow-up. This patient was seen by his family physician until 1 year ago, at which time he had had no recurrence of symptoms, was perfectly well and was working. We had an opportunity to examine him in January 1947. He had no recurrence of symptoms at that time and a roentgenogram taken then was negative.

It is of interest to note a cure in this case without obliteration of the multiloculated cavity at the time of discharge. We consider it an error to take such risk.

CASE 9. F. H., male, age 40, was admitted to the hospital March 28, 1945, discharged April 17, 1945. Diagnosis: (1) empyema loculated right; (2) fistula bronchopleural.

In April 1944, the patient developed a productive cough, dyspnea on exertion, pain in the right chest, ankle edema and easy fatigue. In September 1944, he had an appendectomy followed by a subdiaphragmatic abscess which was drained. In October 1944, he states that his chest was also drained shortly thereafter but only one scar is visible. The cough has persisted since. Examination revealed dullness in the right chest posteriorly up to the seventh rib with decreased breath sounds. Roentgenogram March 28, 1945, showed a large hydropneumothorax in the right base extending to about the seventh rib posteriorly. May 3, 1945, roentgenogram showed no fluid in the right base since the examination 3

weeks previously. Pneumonitis in the right lower lobe was clearing.

The patient had occasional morbidity with temperature reaching 100 degrees as on the day of admission. On March 29, 1945, the day after admission, thoracentesis was done and 350 cubic centimeters of fluid were removed which grew anaerobic nonhemolytic streptococci. The fluid was nonodorous. It was repeated on March 31 and April 6, 1945. Penicillin 40,000 units was instilled on the first tap and 20,000 units on each of the following taps. Cultures were sterile after the third tap on April 6, 1945. Morbidity disappeared rapidly and the patient improved markedly. His sputum volume had dropped from 300 cubic centimeters to zero in 6 days. No sulfonamides or systemic penicillin were given.

Follow-up. Unfortunately we have no follow-up roentgenograms of this patient; however, we have had two communications from him in which he stated he had numerous lower respiratory infections, probably on the basis of his residual parenchymal disease. He has had no episodes which resemble his previous attacks and is fever free and symptom free for long periods of time between these infectious episodes. He will not return for further study but probably has right lower lobe bronchiectasis.

CASE 10. H. R., male, age 30, was admitted to the hospital June 5, 1945, discharged July 19, 1945. Diagnosis: empyema loculated right.

The patient was well until 14 days before admission at which time he began to feel weak and listless and on May 26, 1945, he developed nausea. The symptoms increased and he developed a dry, non-productive cough and had a gradual increase in temperature which on admission was 104 degrees. Examination revealed limitation of expansion of right chest, dullness from sixth thoracic down in the right axillary region with impairment of voice and breath

Fig. 6. Case 31. On August 22, 1945 fluid in right pleural space 1 month after right lower lobectomy for bronchiectasis.

sounds. Crackling rales were also heard in this area. Roentgenogram June 6, 1945 revealed a large fluid collection in the right pleural space possible empyema which appeared to be loculated. On June 18, 1945 roentgenogram revealed an empyema loculus 8 by 4 by 4 centimeters. There was also another loculated collection at the right base more posteriorly situated (Figs. 8 and 9).

His temperature on admission was 103 degrees and his pulse 140. He was given sodium sulfadiazine intravenously for 2 days and sulfadiazine orally for 4 days. Penicillin 350,000 units daily was given from June 6 to 25, 1945. He received thoracenteses daily from June 6 to 18, 1945 with evacuation of all available pus and instillation of 50,000 units of penicillin. On the first tap 550 cubic centimeters of pus were removed. On aerobic and anaerobic culture the pus showed hemolytic and nonhemolytic streptococci. These were present in all specimens obtained. The patient showed slight improvement after the first few thoracenteses, but improvement was slow and his temperature never reached normal. On June 18, 1945 it was decided to do an open drainage because of continued positive cultures, and at this time a second partially drained loculus over the diaphragm was discovered. The patient improved rapidly after drainage and was discharged 1 month later.

Follow-up. The patient was seen in the hospital on September 7, 1945 with no recurrence of symptoms. Follow-up films showed complete resolution of the empyema and only minimal pleural thickening. Letters up to April 1, 1946 stated that he had had no recurrence of symptoms.

CASE 17. A male age 64 was admitted to the hospital July 19, 1945 discharged August 26, 1945. Diagnosis (1) bronchiectasis (2) empyema loculated right, putrid.

The patient was well until October, 1941 when he developed pneumonia from which he recovered, but 4½ months later he again developed pneumonia from which he recovered after a long period of convalescence. He stated that his temperature never returned to normal. He was admitted to a hospital on July 22, 1942 and a diagnosis of left lower lobe bronchiectasis was made. His symptoms which had continued until his admission on July 19, 1945 were weakness, poor appetite and fever. Examination revealed dullness to percussion in the right base posteriorly with crackling rales in both bases a scar from previous drainage on the left tachycardia with questionable cardiac enlargement. Roentgenograms on July 30, 1945, showed abnormal density in the right lower hemithorax on the basis of marked pleural disease. Empyema was not suggested by these films. August 7, 1945 films revealed a well demarcated empyema loculus in the right base in the midclavicular line. On August 22, 1945 the pleural parenchymal disease in the right base appeared to be stationary and only the possibility of fluid in the old empyema loculus previously described was noted.

On admission the patient was markedly debilitated with a septic type of temperature reaching 103 degrees daily. On July 19, 1945 he was placed on penicillin systemically 100,000 units intramuscularly being given daily and this was increased to 300,000 units August 2, 1945. On August 7, 1945 a loculated empyema was discovered and treatment by aspiration and instillation of penicillin was begun. Aspiration on August 8, 1945 obtained 40 cubic centimeters of grayish yellow putrid pus, and 100,000 units of penicillin were instilled. This pus never showed any organisms on smear or culture. On August 9, 1945 a small amount of thick pus was aspirated, the cavity was irrigated and 100,000 units

Fig. 11 Case 12 M. L. on September 6, 1945, 15 days after admission and 12 days after last tap. Follow-up 4 months later revealed no symptoms and roentgenogram showed minimal pleural thickening.

of penicillin instilled. On August 12 and 13, 1945, small amounts of pus were obtained and 50,000 units of penicillin instilled on each of these days. Thoracentesis was again attempted on August 14, 15 and 16 but no fluid could be obtained and no penicillin was instilled. Morbidity dropped sharply after the first instillation of penicillin; his temperature reaching 98.3 degrees on August 9, 1945, and remaining normal from that day until discharge. The original pus was definitely putrid.

Follow-up. This patient was seen by us on November 12, 1946, 15 months after discharge and had no complaints except the persistent chronic cough. He was getting regular bronchoscopic aspirations for his bronchial disease. His appetite was good and on physical examination he was well nourished. There was slight impairment of resonance in the left base and impairment of breath and voice sounds. Tactile fremitus was increased in the same area, and a few moist râles were also present at the right base. Physical examination was otherwise essentially negative. Roentgenograms taken on November 12, 1946, showed evidence of bilateral bronchiectasis. The pleural disease remained minimal.

CASE 12. M. L., female, age 20, was admitted to the hospital August 22, 1945, discharged September 11, 1945. Diagnosis: (1) bronchiectasis, right lower lobe; (2) empyema, loculated, putrid, right, post-lobectomy.

The patient had a right lower lobe lobectomy for bronchiectasis in July, 1945. Her postoperative course was relatively uneventful, however at the time of discharge a small fluid collection was noted on the right side. At this time the fluid aspirated was sterile. One week before the present admission the patient developed fever, chills, nausea, vomiting and productive foul-smelling cough. She was readmitted for further study. Examination revealed a right-sided scar and slight deformity of a missing rib. There were fine râles posteriorly on the right. Vocal resonance was increased in the interscapular

region down to the seventh interspace but from here to the 12th rib it was decreased. Anteriorly over the right lung fine râles were heard. There was marked tenderness over the lower right chest posteriorly. Roentgenograms August 22, 1945, revealed a large empyema on the right. On September 6, 1945, the films showed marked improvement and much of the abnormal density in the right lower lung field had disappeared. Considerable pleural thickening was still apparent along the right lateral chest wall but no fluid was present at this time.

The patient was tapped on the day of admission, August 22, 1945, and 180 cubic centimeters of very thick, foul, bloody pus were removed with no air. Penicillin, 100,000 units, was placed in the cavity. The tap was repeated on August 23, 24 and 25, 1945. The amount of penicillin instilled was 100,000 units on the first two taps and 50,000 units on the last two taps. Systemic penicillin, 240,000 units intramuscularly daily, was given from August 22 to September 11, 1945. Bacteriology showed anaerobic nonhemolytic streptococcus present in the empyema fluid. Cultures were sterile after the second tap.

Follow-up. This patient was last seen in January, 1946, 4 months after discharge, at which time there was no evidence of recurrence of the empyema. The patient had no complaints and roentgenogram at this time showed the chest to be clear with a minimal amount of pleural thickening at the right base. The succeeding year brought no further symptoms.

CASE 13. J. W., male, age 29, was admitted to the hospital September 7, 1945, discharged October 5, 1945. Diagnosis: empyema, loculated, left, putrid, postlobectomy.

Approximately 6 weeks before admission the patient had a left lower lobe and segmental left upper lobe lobectomy for bronchiectasis. His postoperative course was uneventful. A hydropneumothorax present on the left was aspirated on numerous occasions and all of the fluid was found to be sterile. He was discharged about 1 month previous to this

admission. Shortly thereafter he developed a productive cough and recurring bouts of fever. Examination showed a patient of poor nutrition of pale color and with some degree of exophthalmos. His chest revealed a healed scar of the previous left lower lobe lobectomy. Over the left lower chest the breath and voice sounds were decreased. Moist rales and wheezing were heard over the rest of the left chest. The right chest was clear. Roentgenograms September 8, 1945, revealed a large pleural collection in the left chest posteriorly with evidence of fluid extending from the diaphragm to the seventh interspace. October 4, 1945 (discharge film) showed residual pleural thickening and a small amount of fluid.

The patient was begun on systemic penicillin on September 9, 1945 and continued on it until September 29, 1945 receiving 150,000 units daily intramuscularly. His temperature on admission was 102.2 degrees, with an increased pulse and respiratory rate. This increase returned to normal on the first day of penicillin systemic therapy. Thoracentesis was first done on September 10, 1945, 315 cubic centimeters of slightly odorless pus being removed from the left base and 100,000 units of penicillin being instilled. This dosage was repeated on September 11, 1945 and 100,000 units of penicillin were instilled. Aspirations were again done on September 12, 13, 17, 18, 19, 20, 22 and 24 at which time only 50,000 units of penicillin were instilled. Although the size of the cavity was decreasing according to the amount of fluid and air removed, the cultures persistently revealed a hemolytic *Staphylococcus aureus* through out all this time. On September 25, 1945 penicillin and a gram of sulfathiazole microcrystals were instilled in the chest after aspiration. Taps were continued on September 27, 28, 29 and 30. Sulfathiazole was again instilled on September 29, 1945 and again on October 3, 1945. On the other taps 100,000 units of penicillin was instilled. The culture became sterile after the tap of September 29, 1945 and remained sterile on September 30, 1945 and October 3, 1945. This organism was found to be only moderately susceptible to penicillin but susceptible to sulfonamides. At the time of discharge, the cavity could not be entered and on the previous tap only 6 cubic centimeters of yellowish nonodorless thin fluid were removed. It is of interest to note that this patient's culture remained consistently positive while on penicillin, but rapidly became sterile on two instillations of sulfathiazole.

Follow-up: Since his discharge film, which was not too satisfactory, this patient has had a good follow-up series with no evidence of an empyema cavity. His sputum volume remained approximately the same but this was attributed to his slight contralateral bronchiectasis. On January 16, 1946 when he was readmitted for removal of nasal polyps the chest was clear and roentgenogram showed no evidence of recurrence of the empyema. He was seen 3 months later on a routine follow-up visit and had no evidence of recurrence.

CASE 14. B. K. female age 58 was admitted to the hospital November 21, 1945 discharged December 22, 1945. Diagnosis empyema, interlobar right, streptococcal postpneumonic.

Two months before admission the patient was treated for right lower lobe pneumonia with sulfonamides and penicillin. The fever continued and the symptoms returned quite severely 1 week before admission. There was a productive cough with reddish brown sputum. Examination disclosed rhonchi throughout both lung fields, percussion note normal throughout, a marked arrhythmia with extrasystoles and a question of gallop rhythm. Roentgenograms, November 23, 1945 showed a sharply circumscribed fluid collection with air above it in the right hemithorax posteriorly just above the lung root. The most likely diagnosis was an interlobar loculated empyema. December 18, 1945 roentgenogram showed marked improvement in the roentgen appearance of the pleural disease with disappearance of the fluid.

The patient was seen in consultation on November 26, 1945 and was placed on systemic penicillin, 100,000 units daily intramuscularly until December 20, 1945 and penicillin inhalations by aerosol four times daily from November 27, 1945 to December 21, 1945. On November 26, 1945 aspiration of 20 cubic centimeters of pus was done and 25,000 units of penicillin were instilled into the cavity. This was repeated three times in the next 11 days, 20,000 units of penicillin being instilled each time. Cultures showed a hemolytic and nonhemolytic streptococcus. These organisms were present in all cultures obtained. However, no culture is available for the last two taps. At the time of discharge the patient was markedly improved clinically.

Follow-up: She was seen in the Out Patient Clinic in August, 1946 at which time she had no complaints, no cough, no hemoptysis, and no chest pain. A roentgenogram taken at this time showed no pathology except for accentuation of the upper lower lobe septum on the right.

CASE 15. C. S. female age 27 was admitted to hospital December 3, 1945 discharged May 8, 1946. Diagnosis (1) bronchiectasis, left lower lobe; lingula left upper lobe; (2) empyema postlobectomy, left putrid multilocular; (3) fistula bronchopleural.

This patient had suffered since childhood with a cough which was productive of yellowish purulent sputum. A foul odor was present at times. In the past year the symptoms were more pronounced. She also noted profuse purulent nasal discharge and failure to gain weight. Physical examination revealed an extremely thin and rather tall pallid girl. There was limitation of excursion, dullness and harsh breath sounds in the lower left chest. Bronchograms, December 7, 1945 revealed advanced fusiform and sacular bronchiectasis in the left lower lobe and to a lesser degree in the lingula of the left upper lobe.

Lobectomy of the left lower lobe and the lingula portion of the left upper lobe was performed on December 19, 1945 when a rubber tube drain with

negative pressure was placed in the thoracic cavity. This drain was removed on December 23 1945. A thoracentesis was done on December 26 1945 and 240 cubic centimeters of bloody serosanguineous fluid and some air were removed. Repetition on December 29 1945 removed 50 cubic centimeters of serosanguineous fluid. On January 1, 1946 60 cubic centimeters of serosanguineous fluid and 150 cubic centimeters of air were removed. No penicillin was instilled during any of these taps and the cultures were sterile. However the postoperative fever continued with the temperature spiking as high as 103 degrees each day. On January 5 1946 60 cubic centimeters of feild thick pus were obtained but no penicillin was instilled and culture on this material showed *Hemophilus influenzae*. The tap was repeated on January 6 1946 and 50 cubic centimeters of viscid bloody pus were removed with some air and 50,000 units of penicillin were instilled. On January 7 1946 the tap was repeated a few cubic centimeters of bloody fluid were removed and 40,000 units of streptomycin were instilled. On January 8 1946 40 cubic centimeters of purulent nonodorous material were removed and 50,000 units of streptomycin were instilled. On January 9 1946 30 cubic centimeters were removed and 50,000 units of streptomycin were instilled. This was repeated on January 10 1946 after 50 cubic centimeters of fluid were removed. At this time another cavity was entered anteriorly and cloudy purulent looking material was removed. Culture of this material showed bacilli but no other organisms. This cavity was again entered on January 12 1946 when 35 cubic centimeters of pus were aspirated and 50,000 units of penicillin were instilled. At this time, the fluid from the posterolateral cavity which previously grew the *Hemophilus influenzae* appeared to be sterile grossly and no streptomycin being available none was instilled at this time. On January 13 1946, it was decided that due to the patient's poor clinical response thoracostomy should be done with insertion of drainage tubes. The patient's course following drainage was poor and protracted, her temperature spiking as high as 104 degrees daily at first and gradually returning to normal following two more attempts at more adequate drainage of this multilocular empyema cavity many bronchoscopies and much supportive therapy.

Postoperative roentgenograms showed the development of a multiloculated empyema with a large superior-anterior pocket and a posterolateral pocket. These cavities gradually resolved under open drainage. On April 18 1946 the drainage tubes in the left hemithorax were visible. The left upper lobe appeared to be occupying the remaining space within the left hemithorax. There appeared to be slight increase in the pleural thickening in the axillary region but no fluid collections were seen to suggest an undrained pocket. The patient received systemic penicillin from December 7 1945 150,000 units daily intramuscularly until January 9 1946 when the dosage was increased to 350,000 units intra-

muscularly daily and continued until February 8 1946. Sulfadiazine was begun on January 10 1946 and continued until January 21 1946 6 grams daily by mouth. She was finally discharged on May 8 1946 with obliterated empyema space no symptoms, and normal temperature.

Follow up. This patient has been seen in the Out Patient Department and continues well for 6 months with no evidence of recurrence. Follow up roentgenograms showed no evidence of recurrence of pleural disease.

Of interest in this patient is the multilocular character of the empyema the presence of penicillin resistant organisms in both pockets and the marked difficulty in adequately draining these pockets even by direct operative approach.

CASE 16. J. A. male age 16 was admitted to the hospital February 2, 1946 discharged February 17 1946. Diagnosis (1) empyema loculated left (2) fistula bronchopulmonary.

The patient was well until December, 1945 when he developed a cough and pains in the chest accompanied by chills and high fever. His family physician diagnosed pneumonia and treated him at home with sulfonamides with moderate but partial improvement. His weakness persisted and his high fever returned about the middle of January with much more chest pain. He was admitted to the hospital for further investigation. Examination revealed the chest symmetrical with a suggestion of lag on the left. There was dullness to percussion in the left lung below the fourth rib anteriorly and below the sixth rib posteriorly. Numerous crackling râles were heard in this area and there were diminished voice and breath sounds. The right lung was clear. Roentgenograms February 4, 1946 revealed abnormal density of the left lower lung field which we believed to be due to a loculated hydropneumothorax. February 14 1946 improvement had occurred and a thin layer of air was seen between the visceral and parietal pleura in the lateral aspect of the left lower pleural space. There was marked thickening of both layers of pleura. The adjacent parenchymal disease was much less.

Systemic penicillin was begun on February 3 1946, 200,000 units intramuscularly daily in two-hourly doses and was continued until February 17 1946. Thoracenteses with aspiration of pus and instillation of 100,000 units of penicillin, were done on February 3 9 11 13 and 14. The initial size of the cavity was 100 cubic centimeters. The material removed was thick and nonodorous. There were no positive bacteriologic reports however one specimen of pleural fluid which was sent to pathology came back with the diagnosis of empyema from the cells and debris which were found. At the last tap on February 14, 1946 only a few cubic centimeters of thin amber-colored fluid were obtained. The sputum volume which had been 600 to 900 cubic

centimeters per day, decreased to 1 to 10 cubic centimeters per day, and the patient rapidly improved.

Follow up. This patient was seen 2 months after discharge in the Out Patient Clinic. He had no complaints. Physical examination revealed marked clearing of the left lower chest and the roentgenogram was almost normal. The cavity had disappeared and pleural thickening was minimal. Sputum volume remained zero to 10 cubic centimeters per day. We have had no further contact from this patient.

CASE 17. W. D. male age 46 was admitted to the hospital April 6, 1946, discharged May 13, 1946. Diagnosis (1) empyema, loculated left putrid postpneumonic (2) fistula bronchopleural.

The patient's symptoms began in October, 1945, with malaise, chills, and fever. He was hospitalized and a diagnosis of pneumonia with pleurisy was made. During the 9 weeks of hospitalization he received numerous thoracenteses with aspirations of fluid. Penicillin systemically was given but not topically. At the end of 9 weeks he was sent to another hospital for bronchoscopy and remained there a short time without a diagnosis being made. He returned home for 3 months on no treatment, and during this time he went progressively downhill with productive cough, weight loss, chills, fever, and pain in the chest. Examination revealed a markedly debilitated and emaciated 46-year-old white male obviously seriously ill. His color was grayish. He had an old thyroidectomy scar and the trachea was deviated to the right. On the left, expansion was markedly decreased. There was dullness to percussion and the breath and voice sounds were decreased. Roentgenograms April 9, 1946, revealed a large loculated empyema with a fluid level at the left sixth interspace situated posteriorly. There was also what appeared to be a subaternal extension of the rod gland into the superior mediastinum. June 27, 1946, the pleural loculus previously noted had further decreased. There was pleural thickening throughout the left chest. The upper mediastinal mass was still present. There was stringy density in the left lung root.

On admission this patient was so weak and debilitated he could not move out of bed. His temperature was 101° degrees, his pulse 100 and respiration 30. Thoracentesis of this large loculated pyopneumothorax was done on April 6, 1946, the day of admission when 1200 cubic centimeters of foul thick pus were removed from the left pleural space and 100,000 units of penicillin were instilled. This treatment was repeated on April 7, 8, 9, 10, and 12 by which time the size of the cavity was 5 cubic centimeters. On April 14, 16, 18, 21, and 27 large amounts of air were removed but no fluid until the taps on May 3 and 7, 1946, when 100 cubic centimeters of fluid and 30 cubic centimeters of air were removed. Penicillin 100,000 units was instilled on each of these taps. No other thoracenteses were done. On culture hemolytic streptococcus intestinal type, was found on the first specimen but no anaerobic

culture was made. All other specimens were sterile. The patient's temperature dropped rapidly to normal after the first tap, the size of the empyema cavity decreased rapidly, and clinically he improved remarkably. No systemic penicillin was given.

Follow up. Two weeks after discharge the patient was readmitted to the Orthopedic Service, and roentgenograms taken at this time showed complete obliteration of the cavity and only residual pleural thickening. He was seen again by us on August 10, 1946, at which time his symptoms were minimal and he was able to return to work.

CASE 18. W. A. male age 56 was admitted to hospital May 26, 1946, discharged July 9, 1946. Diagnosis (1) carcinoma pulmonary left (2) empyema loculated left.

Symptoms of back pain, fever, malaise, and pain in the left chest had been present since April 6, 1946. The patient was treated in a local hospital with penicillin and sulfonamides with some improvement. During this time he had occasional productive cough and some hemoptysis. He was transferred for further study. Examination revealed dullness to percussion and absent breath sounds over the left chest up to the seventh thoracic, with tubular breathing at the apex. The physical examination was otherwise essentially negative. Roentgen-ray examination revealed the following: outside films, the last one on May 4, 1946, showed a roughly spherical mass in the extreme posterior portion of the left lower lobe. Admission film on May 18, 1946, showed evidence of left lower lobe mass which was similar to that seen on the outside film and had increased in size. There was evidence of fluid in the pleural space.

Aspiration removed 70 cubic centimeters of thick, yellowish, nonodoriferous pus, the culture of which grew a pneumococcus which could not be typed. Penicillin was begun systematically on June 1, 1946, in the dosage of 50,000 units every 3 hours intramuscularly and continued until July 5, 1946. The empyema cavity was tapped and 70 cubic centimeters of pus removed on June 1, 1946. Aspiration was repeated on June 2, 3, 4, and 7. At each tap, 100,000 units of penicillin were instilled. On June 1, 1946, another tap removed 3 to 4 cubic centimeters of noninfected fluid. No penicillin was instilled. The last thoracentesis attempted was on June 18, 1946, at which time no cavity could be found. After the first tap all other thoracentesis material was sterile. A left pneumonectomy was done on June 30, 1946. No empyema cavity could be found, and the pleura while thickened showed no signs of active inflammation. The patient's postoperative course was uneventful and he was discharged approximately 3½ weeks following the pneumonectomy.

Follow-up. The patient was seen in the office in October, 1946. There had been no postoperative infection in the resected side. He was feeling well but roentgenogram revealed extension of the carcinoma to the opposite lung. Since then this patient has expired from widespread metastatic carcinoma.

CASE 19. M. H. age 61 was admitted to hospital July 14, 1946, discharged August 16, 1946. Diagnosis (1) empyema loculated left (2) fistula bronchopleural (3) bronchiectasis upper middle and lower lobes right.

The chief complaint was of cough with blood streaked sputum. He was well until December 15, 1945, when he developed a cold. This persisted for several days until he became acutely ill and was confined to bed for 5 weeks. Weight loss, sepsis and productive cough have continued ever since. On physical examination the temperature was 99 degrees, pulse 115 and respiration 32. The patient was markedly emaciated. There was anterior cervical adenopathy and the trachea was deviated slightly to the right. The lungs were emphysematous and there were diminished breath sounds and tactile fremitus over the right base posteriorly. There was some mediastinal shift toward the right. Roentgenograms July 15, 1946, revealed a large loculated fluid collection in left posterolateral chest with fluid level indicative of bronchopleural fistula. August 1, 1946, bronchogram showed extensive saccular bronchiectasis. August 9, no empyema cavity was visible.

Course. This patient was first seen by the Surgical Department on July 14, 1946, at which time thoracentesis was done and 500 cubic centimeters of thick, nonodorless, greenish yellow pus were removed. In exhaustible amounts of air were also obtained. Penicillin, 100,000 units in 25 cubic centimeters of saline was instilled and systemic penicillin, 300,000 units daily was begun and continued until August 16, 1946. Aspiration was repeated on July 18, 1946, and 500 cubic centimeters of fluid were removed. Evidence of a bronchial fistula was again present. Aspirations were continued on the following days: July 19, 20, 22, 23, and 24, the amount of fluid becoming less and thinner on each of these taps and 100,000 units of penicillin being instilled each time. The taps were continued with instillation of only 50,000 units of penicillin on July 25, 27, 29, 31, and August 2 and 5. At the time of the last tap only 10 cubic centimeters of air and 2 cubic centimeters of thin, clear fluid were removed from the cavity. Clinical response was rapid and marked during these thoracenteses and his productive cough cleared rapidly; his appetite returned and he gained weight. He was strong enough to get out of bed, which he had been unable to do before. None of the specimens of pleural fluid showed any growth. This is interesting since the fluid obtained was grossly pus and for at least six of the taps there was an open bronchial fistula.

Follow up. On October 18, 1946, this patient was well weighed more than he had for a number of years and had returned to work. His chronic cough persisted but this was probably on the basis of his underlying bronchiectasis. A roentgenogram taken on October 18, 1946, 4 months following treatment showed no evidence of pleural disease.

CASE 20. I. R. male, age 56 was admitted to hospital October 29, 1946, discharged November 30, 1946. Diagnosis empyema, loculated right.

This patient had a previous admission on August 16, 1946, and was discharged on September 6, 1946. Three months before the first admission the patient noted a knife-like pain in the right chest which was worse upon breathing or coughing. The cough was productive of greenish sputum and he had some night sweats. Examination revealed decreased to absent breath sounds with dullness below the line of the scapula on the right. Roentgenograms August 16, 1946, showed a bilateral pleural effusion more marked on the right with atelectasis of the right upper lobe out of proportion to the effusion and rounded mass in the right lower lobe area. During this first admission the patient received intramuscular penicillin 240,000 units daily and thoracentesis on August 19, 1946, removed 20 cubic centimeters of putrid purulent material from the right chest. Penicillin 200,000 units was instilled. Bacteriology studies revealed many anaerobic nonhemolytic streptococci. On September 5, 1946, aspiration of a few cubic centimeters of similar material without instilling penicillin was done. The patient was discharged on September 6, 1946, with the cavity still present. At the time of his readmission on October 29, 1946, the patient still had fever and a productive cough. On November 1, 1946, the right chest was again aspirated, and 80 cubic centimeters of greenish brown fluid with no odor were removed. Bacteriology report on fluid obtained showed a moderate number of *Streptococcus viridans*. Because of roentgen ray findings of an additional mass in the right chest surgical consultation was obtained and exploration of the chest was done on November 18, 1946, revealing only diaphragmatic loculus of empyema which was drained. A biopsy of pleura showed no neoplasm. Streptomycin and penicillin were instilled through the tube daily for 10 days, then the tube was removed. Patient recovered rapidly.

Follow up. Up to August 25, 1947, approximately 8 months later, the patient was free of symptoms, was gaining weight and had only slight residual right pleural thickening as shown by roentgenogram.

This patient was treated very inadequately for the 3 months prior to his transfer to surgery. Aspiration was done only twice on his first admission and once on his second hospitalization, although small quantities of putrid pus were obtained each time. On the first and third of these penicillin 200,000 units was instilled. Neither active treatment of the known right empyema or proper proof of the suspected tumor was accomplished. The left effusion was never tapped but disappeared under bedrest, supportive treatment, and systemic penicillin. This case emphasizes the necessity of such patients being treated by the surgeons and is an example of some of the failures reported in other articles.

SUMMARY AND CONCLUSIONS

The thorough aspiration of pus from empyemas and the reinstallation of adequate amounts of an appropriate antibiotic agent satisfy the basic principles of treatment of this disease namely sterilization and obliteration of the cavity which can be accomplished in most cases and re-establishment of pulmonary function thus decreasing morbidity. In the few instances in which the patient does not react satisfactorily surgical drainage is delayed very little.

In 20 patients treated by us and followed for from 6 to 36 months cure was obtained in 80 per cent while 20 per cent required surgical drainage.

Details of a logical and proved technique are described and the contraindications given.

The literature on the subject is briefly analyzed.

The necessity for proper surgical training in order to treat empyema properly by this or other method is emphasized.

THE EFFECT OF STREPTOMYCIN IN EXPERIMENTAL STRANGULATION OF THE BOWEL

H A DAVIS M D F.A.C.S., J GASTER, M D R. L. MARSH M D and
P. A. PRITEL, M D., Los Angeles, California

STRANGULATION of the bowel has been for many years both a diagnostic and a therapeutic problem in surgery. The mortality rate is still high despite the value of intestinal suction, restoration of the fluid and electrolyte balance and sulfonamides. In experimental bowel obstruction penicillin has proved to be only moderately effective in prolonging life. Streptomycin is of particular value because it is effective against certain pathogenic bacteria which are not susceptible to the action of other antibacterial substances.

The present study was undertaken to determine what effect if any was exerted by streptomycin upon the course of experimental strangulation of the bowel in rabbits. We were also interested in ascertaining the extent to which bacteria contribute to the damage of the intestine resulting from an inadequate blood supply.

REVIEW OF THE LITERATURE

It might be helpful at this point to review briefly the literature on the actions of streptomycin as they pertain to the present study. Waksman and his associates (28, 6) have shown that streptomycin is effective against certain gram negative, gram-positive and acid fast organisms. Finland and his coworkers have pointed out that many organisms which at first are sensitive to streptomycin may rapidly become resistant. This fact emphasizes the importance of using streptomycin in doses adequate to produce levels in the tissues and body fluids well above the minimum effective concentration.

The parenteral administration of strepto-

From the Hunterian Laboratory, the Department of Surgery and the Graduate School of Medicine, College of Medical Evangelists, Los Angeles, California.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, New York, September 8 to 12, 1947.

mycin can result in a therapeutic blood level which reaches its peak in 1 to 2 hours and then gradually falls off. Sixty to 80 per cent of the drug is excreted in the urine in 24 hours (21, 30).

There is no absorption from the stomach or bowel. Although streptomycin is less effective in the presence of acids or acid urine, it is not inactivated by gastric juices (1) and when given orally is excreted almost entirely in the feces. Large concentrations appear in the feces with a considerable reduction of *Bacillus coli* and other organisms generally present there (20, 9). Good concentrations of the drug appear in the pleural and peritoneal fluids, bile, aqueous humor, and the fetal circulation (21, 30).

Streptomycin is polyvalent to a much greater degree than penicillin or sulfonamides and its effectiveness against many strains of organisms of the colon group differentiates it sharply from penicillin (22, 25). Murphy and his colleagues have demonstrated that this property of streptomycin renders it valuable in the treatment of acute diffuse peritonitis caused by a mixture of gram positive and gram negative bacteria.

The extent to which intestinal bacteria contribute to the damage to the intestine produced by an inadequate blood supply has not been clearly demonstrated. The recent work of Poth and his group (12, 14, 15, 16, 17, 18, 19) has shown that sulfasuxidine and sulfathiazole have a powerful antiseptic effect on the intestinal flora. Sarnoff and his coworkers (23, 24) concluded that succinylsulfathiazole conferred a protective effect on a 50 centimeter segment of ileum with occluded venous return by preventing perforation and permitting recovery of bowel integrity.

Harper and Blain (7) observed that in dogs with isolated obstructed, jejunal loops death

Fig. 1 Effect of streptomycin on mortality rate from bowel strangulation in rabbits.

was due to the action of bacteria or their products, and furthermore that these animals could be protected for a significant period of time with large doses of penicillin. Sulfasuxidine likewise gives protection in dogs with isolated jejunal loops (13, 8).

Callihan, Kennedy and Blain (3) emphasized the fact that bacteria play an important part in maintaining the present mortality rate in intestinal obstruction at approximately 20 per cent.

Many investigators (26, 27, 29) have stressed the significance of hemorrhage in shock accompanying strangulated bowel obstructions. In order to study the precise rôle of bacteria Sarnoff and Fine (23), Blain and Kennedy (2) and others excluded the factor of reduction of the blood volume by treating the shock that developed in their control and experimental animals. While recognizing the significance of hemorrhage and shock, Blain and Kennedy (2) were of the opinion that the bacterial factor was of major importance in causing death from strangulated intestinal obstruction since the survival time was prolonged by penicillin. The prolongation of life however though striking was only moderate. Their control animals died within 36 hours. Seven dogs with the same operation plus massive doses of penicillin survived between 50 and 100 hours. Six dogs lived 70 hours or longer and 4 dogs, 90 hours or longer. In addition they performed intestinal resections on 5 animals at the end of 72 hours which is twice as long as the sur-

vival time for the animals not treated with penicillin and 4 of these animals lived indefinitely.

MATERIALS AND METHODS

In the present experiments rabbits were used because as Noer has shown their mesenteric vascular pattern is more similar to that of man than is the mesenteric vascular pattern of dogs. It was necessary to use a method of producing bowel strangulation which would not introduce the factors of hemorrhage shock and intestinal obstruction to complicate the results and render it difficult to determine (1) the exact action of atreptomycin upon strangulation unaccompanied by intestinal obstruction (2) the significance of bacterial growth in producing death from strangulation. For these reasons strangulation by devascularization of the small bowel was the method chosen. The first problem was to ascertain the minimum amount of devascularization of the bowel which would cause death in a high percentage of the animals.

Devascularization was performed by ligating the arcuate artery and vein close to the wall of the ileum at two points of varying distances and then ligating all the intervening blood vessels so that the only blood to the devascularized area came through the fine intramural vessels at each end. No attempt was made to suture the mesentery because of its thinness. Fifty-two rabbits were operated upon under ether anesthesia and varying lengths of ileum were devascularized. It was demonstrated (5) that devascularization of 7.5 centimeters of ileum was the smallest length of devascularization associated with a consistently high mortality rate. The average weight of the rabbits in this series was 2 kilograms.

Four groups of rabbits were used. The first was the control series (10 rabbits) in which 7.5 centimeters of bowel was devascularized. The second group (8 rabbits) had 7.5 centimeters of bowel devascularized and each rabbit was given a single daily subcutaneous injection of 80 milligrams of streptomycin for a period of 25 days. The first injection was given immediately after completion of the devascularization operation.

Fig. 2. Gangrene of ileum in untreated rabbit showing site of perforation (bracketed). Note opening in mesentery.

The third group (12 rabbits) had 7.5 centimeters of bowel devascularized and each rabbit was given 200 milligrams of streptomycin daily for 7 days followed by 100 milligrams of streptomycin daily for 21 days, given in the form of two subcutaneous injections daily. The first dose was injected immediately after completion of the operation.

The fourth group (5 rabbits) received 100 milligrams of streptomycin daily by subcutaneous injection for 4 days. They were then subjected to devascularization of the bowel (7.5 cm) and continued to receive 100 milligrams of streptomycin daily for a total period of 25 days.

RESULTS

The effects of varying doses of streptomycin upon the mortality rate in experimental strangulation of bowel in rabbits are presented in Figure 1. The control group of 10 rabbits which had not received streptomycin were dead by the nineteenth day after operation. Postmortem examination disclosed that perforation with peritonitis was the cause of death in 80 per cent of these animals (Fig. 2). In the remaining animals death did not appear to be directly related to the devascularization of the bowel.

In the second group of 8 rabbits given 80 milligrams streptomycin daily the mortality was 62.5 per cent 19 days following operation. There was a definite prolongation of survival time in the rabbits in this group. The deaths could be classified as early and late. The early deaths were due to perforation and peritonitis

Fig. 3. Revascularization of strangulated bowel in streptomycin treated rabbit. Note thickening and increased vascularity of mesentery, the opening in which has closed.

in 2 animals. The late deaths in 3 animals resulted from intestinal obstruction produced by kinking of the devascularized bowel. In 1 animal death was not related to the operation. Two animals are still living.

In the third group of 12 rabbits, given 200 milligrams of streptomycin daily for 7 days and then 100 milligrams daily for 21 days more there has been no mortality after a period of more than 2 months. Five animals were deliberately sacrificed. Postmortem examination disclosed no peritonitis or intestinal obstruction. One animal was alive and apparently well although he had a partial intestinal obstruction.

The changes that take place in the devascularized loops of bowel in those animals which have been enabled to survive by means of streptomycin are of great interest. The 7.5 centimeter loop had contracted to a shorter loop of 5 to 6 centimeters. Blain and Kennedy

Fig. 4. Revascularization of strangulated bowel in streptomycin treated rabbit. Note adherence of vascular omentum to bowel.

(2, 3) have shown the opposite effect, that is the lengthening of a 60 centimeter segment of ileum to 70 or 100 centimeters when the mesenteric veins were tied. The opening in the mesentery had closed spontaneously. Examination of the devascularized loops of surviving animals showed that the blood supply to the devascularized area came from five sources:

1. Adherent loops of intestine
2. Growth of mesenteric vessels. The hole in the mesentery had closed and blood vessels had grown up to the devascularized loop of intestine. Figure 3 shows blood vessels which have grown past a ligature.
3. The omentum which was frequently found adherent to the damaged loop (Fig. 4).
4. Vascularized adhesions between the parietal peritoneum and the devascularized loop of bowel.
5. Collateral circulation through the intramural blood vessels. In the fourth group of 5 rabbits given streptomycin before and after devascularization there was 1 death on the morning after operation but this was due to a hemorrhagic pneumonia and apparently not related to the experimental procedure. The other 4 rabbits survived. One animal was sacrificed and postmortem examination showed the same type of revascularization of the devascularized bowel present in group 3.

DISCUSSION

These results indicate that streptomycin is effective in lowering the mortality rate of rabbits suffering from experimental strangulation of the bowel. If a sufficiently large dose (300 mgm daily) of streptomycin is given there is no mortality. This action of streptomycin in preventing perforation and peritonitis leads us to conclude that in an area of devascularized bowel (strangulation) gangrene and perforation of the bowel are due more to bacterial invasion of the bowel wall than to lack of blood supply alone. The streptomycin by preventing bacterial invasion of the ischemic area, and thus maintaining the anatomical integrity of the bowel wall, allows time for an adequate collateral blood supply to develop.

It is of interest that in some of the rabbits which received smaller amounts of streptomycin (80 mgm daily) the pathologic lesion was

changed rather than eliminated in the sense that it was changed from a bacterial and ischemic gangrene of the bowel wall to a mechanical obstruction due to kinking of the bowel.

In some respects the bowel lesion produced in these experiments is comparable with acute arterial mesenteric thrombosis or embolism which occurs in human beings. In this condition and in other lesions of the bowel in which there occurs a combination of inadequate blood supply and bacterial invasion of the tissues—for example after operative release of a strangulated hernia or after intestinal suture or anastomosis when the vascularity of the tissues at the site of suture is in doubt—the administration of streptomycin may on the basis of the results of the present study prove to be of value.

Finally the question must be asked: How does the streptomycin reach the bacteria present in the devascularized area? There are two possible ways in which this could take place: (1) The streptomycin is secreted into the intestinal tract in effective concentration from the blood stream. It has been shown that streptomycin administered parenterally is not excreted into the intestine. In our experiments streptomycin was not administered orally. (2) The streptomycin is carried in the blood stream along the collateral blood vessels which run from the normal bowel into the devascularized area. This is the probable route. We have shown elsewhere (5) by injection studies that the intramural vessels remain patent and carry blood into the devascularized area of bowel.

If this explanation is correct, namely that the action of streptomycin in bowel strangulation depends upon its being carried to the strangulated area by the blood stream, it follows that the more extensive the area of strangulation the less likely is streptomycin to prove effective in preventing bacterial gangrene and perforation of the bowel wall. In a paper which will be published elsewhere (5) we have shown that the length of survival is directly inverse to the length of strangulated bowel. This would mean that the more extensive the strangulated loop the shorter would be the period of survival and therefore less

time would be available for the streptomycin to exert a beneficial effect.

These facts have a direct clinical application. Since it is usually impossible to predict before operation the extent of strangulation which is present, it would be dangerous to depend upon streptomycin alone even in patients with mesenteric thrombosis. It is clear that streptomycin should be regarded as an adjunct to rather than as a substitute for surgery in strangulation of the bowel.

CONCLUSIONS

The administration of streptomycin in doses of 80 milligrams (40 mgm per kilogram of body weight) daily lowered the mortality rate and in doses of 200 milligrams (100 mgm per kilogram of body weight) daily prevented any mortality in rabbits subjected to experimental strangulation of bowel by devascularization.

Bacterial growth in the devascularized bowel wall was the major factor leading to perforation and gangrene of the bowel. Prevention of the growth of bacteria by streptomycin was the mechanism underlying the prolongation of life in the treated rabbits in these experiments.

On the basis of the results obtained in our study it is suggested that in human beings the administration of streptomycin might be a useful adjunct in the treatment of strangulated intestinal obstruction particularly the type due to acute arterial mesenteric thrombosis or embolism. Streptomycin should be given in intestinal obstruction when strangulation is suspected. It is suggested that the therapeutic value of streptomycin is dependent upon the length of strangulated bowel. Since it is impossible to predict the extent of strangulation streptomycin should be regarded as an adjunct to and not as a substitute for surgery.

III BURIED EPIDERMIS GRAFT

ERNEST BORS M.D., and ALISTIN COMARR M.D. Van Nuys, California

THE purpose of this paper is to revive an old yet simple and efficient method of skin grafting and to discuss its application to the problem of the treatment of bedsores in patients suffering from paraplegia. The procedure has been used for more than 2 years (F. B.) in selected decubitus ulcers. The last series of more than 50 patients treated during the past year form the basis for our observations.

The procedure is known as the Implantation Method of Skin Grafting (Wangensteen). Originated by Braun (56) in 1910 it was applied by Wangensteen for the first time in 1928. In 1930 he reported the technique, indication and result in 60 cases. The series included cases of infection, osteomyelitis, empyema, abscess, decubitus ulcers, and burn. As we have been familiar with the method since 1929, it seemed that we were justified in using it on a larger scale in treating decubitus ulcers in the presence of spinal cord injuries.

The sores treated were situated on the sacrum, trochanter, knees, ankles, pelvis, dorsum and iliac spine. The purpose of the grafting was twofold: first to achieve permanent closure of the ulcer, and second to provide temporary epithelialization in order to restrict the loss of protein until a permanent plastic flap procedure could be attempted. The use of buried epidermis as a permanent graft has definite value in cases in which plastic procedures cannot be executed. The method is well suited for the treatment of ulcers of the heels, ankles, and knee caps.

The preoperative management is similar to though less complicated than the routine preparation for plastic closure of decubitus ulcers. It consists of maintaining the protein balance (14) and correction of anemia (15). Also wet dressings of Dakin's or Domboro's

solution are applied locally to the area involved to enhance good granulation, better granulation tissue provides a better medium for the seeds to develop in. Wangensteen's observation, however, confirms the fact that there is a surprising number of "takes" even when the seeds are implanted in a poor host.

The technique (Fig. 1) is essentially the same as that described by Braun and Wangensteen. After routine preparation of the donor site with ether and alcohol, saline solution is used to keep the skin surface wet. With a #11 Smith or amputation knife a thin Thiersch graft is removed in one piece. Its size depends on the number of grafts needed. The graft is then divided on a wooden board with a Parker knife into small squares of 0.5 by 0.5 centimeter. An instrument is used to drill holes into the granulation tissue at an angle of 35 degrees. The grafts are introduced into the preformed bed where they are retained after withdrawal of the instrument. Instead of the instrument, straight needles can be used as described by Wangensteen. It is best to implant the seeds first into the lowermost row of the field. This step will keep the operative area free of blood. Even the slightest unavoidable hemorrhage from burrholes tends to blur the field if grafting is started on top. The grafts are placed 1 to 1.5 centimeters apart. The grafted area is covered with dry fibrin foam and then dressed with equal parts of furacin and boric acid ointment. A firm bandage is applied for 5 to 7 days. The dressings are changed every other day. Should pyocyanous infection develop despite the prophylactic use of boric acid ointment, acetic acid wet dressings will readily eliminate it. We keep the patient in bed for 48 hours although Wangensteen has applied the method successfully in ambulatory patients. At the end of the first and beginning of the second week, grayish islands (Fig. 2) of epithelium appear at the site of the seeds. The patches coalesce rapidly and granulation tissue retracts. If barren space remains, regrafting can be at

tempted at any stage after the first 10 days. Complete epithelization will take place in from 3 to 6 weeks depending on the size of the defect.

We concur with Wangenstein's statement that the cosmetic result has not been above criticism and we also agree with him that this disadvantage is outweighed by the many advantages. The chief advantages are (1) the simplicity of the method (2) the great number of 'takes' ranging from 50 to 70 per cent (3) the resistance of the implants to infection and extrinsic damage—even where breakdown occurs quick regeneration ensues from the seeds (4) the thriftiness of the method—the donor area in other words the size of the Thiersch graft need be only 6 to 8 per cent of the size of the defect to yield sufficient seeds to bring about healing.

Comparison of the resulting skin with that obtained by marginal epithelization showed it to be firmer and stronger. Under gentle massage the skin revealed a tendency to become mobile. The reason for that might be an imitation of true skin by the seeds (4) which tend to push their epithelium along the cleft created by the implantation. On histologic examination berrylike structures were described (15) consisting of a nucleus of cutis enveloped by a shell of epidermis. This too undoubtedly accounts for easy regeneration.

All these advantages more than outweigh the criticism that the cosmetic results are inferior and that the quality of the resulting skin is inferior to that obtained with plastic flap procedures. It is our opinion, therefore, that in all cases of decubitus ulcer where free skin grafting appears to be indicated the 'buried

THE TREATMENT OF CONGENITAL (OR DEVELOPMENTAL) COXA VARA

THOMAS HORWITZ, M.D. F.A.C.S. Indianapolis, Indiana

ONE must conclude from a critical review of the literature that the treatment of congenital coxa vara is not too well defined. There are those who recommend a period of conservative treatment prior to surgery. It appears logical to these authors (2-10) that protection from direct weight bearing in unilateral cases and the avoidance of the upright position in bilateral cases may lessen the deforming effects which weight bearing and muscle tension have upon the disorganized femoral necks in these cases. Although they report no group of patients so treated, they draw attention to the fact that spontaneous correction has been observed to occur in other types of juvenile coxa vara, for example the rachitic type and also to the fact that a mild varus deformity of the neck of the femur is consistent with good function (Fig. 1).

However, most authors believe that there is no justification for awaiting spontaneous ossification prior to osteotomy and they advise immediate surgical intervention (3). In this latter group there are those who favor (12) and those who advise against (4, 5, 9) drilling or introduction of a bone peg through the femoral neck and epiphysal plate region for purposes of 'revascularization and revascularization' prior to or at the time of corrective osteotomy. Those recommending osteotomy alone point to the fact that overcorrection of the neck deformity to a degree of coxa valga, so as to bring the plane of the capital epiphysal line nearer to the horizontal, has been followed by spontaneous maturation of the epiphysal plate in their patients.

The present investigation is based upon 17 cases of the congenital or developmental type of coxa vara, and it has as its purpose an

evaluation of the results following a variety of surgical procedures. The ages of the 17 patients ranged from $3\frac{1}{2}$ to 21 years at the time of first operation. In 8 patients the condition was bilateral and in 9 it was unilateral.

ANALYSIS OF CLINICAL MATERIAL

The clinical data in the 17 cases of congenital (developmental) coxa vara have been incorporated in Table I. Results were interpreted as being good when pain was relieved, limp and a positive Trendelenburg test lessened or disappeared, the normal lumbar lordosis was restored, the range of abduction of the hip joint was increased and there was restoration of some or all of the length of the affected extremity. The roentgenograms in these cases revealed a restoration of the normal neck shaft angle of the femur. Such results were obtained in 2 cases, one being unilateral and the other being bilateral. Fairly satisfactory results as judged from the facts that some residual deformity and disability persisted postoperatively, often with incomplete correction of the coxa vara deformity on the roentgenogram, were obtained in 4 cases, 2 being unilateral and 2 being bilateral. The results in the remaining cases have been classified as poor.

DISCUSSION

The postoperative results in the 17 cases of congenital coxa vara herein reported have not been uniformly satisfactory after any one method. However, they have been more consistently satisfactory, with a lesser incidence of immediate postoperative complications following subtrochanteric osteotomy than by any other procedure. The poorest results have followed the intra-articular procedures.

The appearance of late complications, such as deformity of the femoral head and degenerative arthritis of the hip joint, was related

From the Laboratory Division, Hospital for Joint Diseases, New York, Henry L. Jaffe, M.D., director. Work done under a Frederick Brown Research Fellowship in Orthopedic Surgery.

Fig. 2.

Fig. 3.

Fig. 2. a, Anteroposterior roentgenogram of the right hip joint in a 1-month-old colored boy with bilateral coxa vara deformity on a rachitic basis. b, Roentgenogram of the same hip 6 years later during which period the child received no orthopedic treatment, shows an overcorrection of the femoral neck deformity with the development of slight coxa valgus. A similar spontaneous correction occurred on the left side. c, Roentgenogram of the right hip joint in an 1-year-old male demonstrating open epiphyses and moderate coxa vara deformity. There has been surgical intervention on this side and the function is excellent. d, Roentgenogram of the left hip joint of the same case as (c) 6 years after drilling operation and subtrochanteric osteotomy. The capital and greater trochanteric epiphyses are closed and the coxa vara deformity is fairly well corrected. Function is excellent and there is only a slight limp on this side.

Fig. 3.

Fig. 3. a, Right hip joint of 7-year-old colored female. There is a marked congenital coxa vara deformity and the region of the vertically placed epiphysal plate and of the adjacent femoral neck shows considerable disorganization. The projecting inferior lip of the femoral neck could be misinterpreted as representing the inferior portion of a displaced capital femoral epiphysis. b, Same hip joint as in (a), 6 years following subtrochanteric osteotomy. The functional result is poor, there being residual limp and considerable loss of motion. The roentgenogram shows a residual coxa vara, and mushrooming of the capital epiphysis with narrowing and irregularity of the joint space superiorly. c, Hip joint of 31-year-old girl with severe bilateral coxa vara deformity 6 years after a subtrochanteric osteotomy. The femoral head is somewhat mushroomed and the joint space is narrowed superiorly. d, Roentgenogram of the right hip joint in the same patient as (c) 35 years after Whitman reconstruction operation for a marked congenital coxa vara deformity demonstrates very advanced degenerative arthritis of the hip joint.

Fig. 3. a, Roentgenogram of the left hip joint of a 7-year-old boy 1 year after replacement of the capital epiphysis on the femoral neck with a bone peg. The capital fragment has collapsed and there is severe distortion of the remains of the femoral head and neck. Clinically the hip joint was ankylosed with flexion-adduction deformity which required subtrochanteric osteotomy. b, Right hip joint in a 7-year-old colored female in whom the bony structures are remarkably well developed. The coxa vara deformity is severe, the inferior border of the femoral head reaching below the level of the lesser trochanter. The femoral neck is somewhat foreshortened, and its inferior beak projects sharply downward as far as the inferior lip of the capital epiphysis. (Continued on next page)

not only to the severity and duration of the coxa vara deformity and to the age of the patient, but, in some of the cases to the surgical intervention. These complications occurred not only following intra articular procedures (Figs. 2 b and 3 a) but followed a combined drilling subtrochanteric osteotomy with revision of the greater trochanter in one case (Fig 3 c and f) and subtrochanteric osteotomy in 3 cases (Figs. 2 a, b d and 3 b c, and d). It is apparent from the writer's material, therefore, that a good clinical result immediately postoperatively is no assurance against the development of secondary degenerative changes in the hip joint later in life. Nevertheless, these changes will certainly appear and at a much earlier age (as early as 15 years in one case in the writer's material) if no effort is made to correct the mechanical disturbance incidental to the coxa vara deformity.

Discussions relative to the technical problems involved in performing a subtrochanteric osteotomy and underlying the rationale of drilling as a procedure directed to revascularizing and revivifying osseous tissue and with reference to the treatment of cases in which a severe degenerative arthritis of the hip joint dominates the clinical picture require special consideration.

The vertical epiphyseal plate and the metaphysis appear fairly well organized. c, Excellent correction of the coxa vara in the case illustrated in, b after subtrochanteric osteotomy. The epiphyseal plate is still visible. d, Roentgenogram of the hip joint in c, 1½ years postoperatively, demonstrates marked alteration in the head and neck of the femur. The bone is markedly densified the neck is broadened due to the deposition of bone on its superior surface, and the head is deformed and its articular surface is irregular. e, An advanced stage of coxa vara deformity in a 14 year old male with unilateral involvement. The neck is markedly foreshortened and the inferior portion of the femoral head is placed opposite the lesser trochanter where it appears to be attached directly to the femoral shaft. There is an irregular radiolucent band between the femoral head and the remains of the disorganized neck, which might be misinterpreted as a site of pseudarthrosis or non union. f, Roentgenogram of the hip joint in the case illustrated in, e, 5 years following a drilling of the neck of the femur subtrochanteric osteotomy and excision of part of the greater trochanter. The immediate correction of the coxa vara was very good, and, in fact, this roentgenogram demonstrates the outlines of the head and neck in the corrected position. There has occurred however an enormous deposition of bone about the femoral neck, particularly at the upper pole of the resected greater trochanter. The femoral head is mushroomed and its articular surface is irregular.

TABLE I—CLINICAL DATA IN 17 CASES OF CONGENITAL COXA VARA

Operation	Age	U Unilateral or Bilateral	Result	Remarks
Subtrochanteric osteotomy	15½	Bilateral (rt.)*	Good	Follow-up 4 years. Drilling osteotomy on left
	11	Bilateral	Fair	Follow-up 4 years
	6½	U Unilateral	Fair	Follow-up 3 years
	7	Unilateral	Poor	Required second osteotomy with fair result
	6	Bilateral	Poor	Pseudarthrosis followed second osteotomy
	7	Bilateral	Poor	Required second osteotomy
	7	Bilateral (rt.)*	Poor	Partial ankylosis of right hip joint. Drilling osteotomy on left
	5	Bilateral (left)*	Fair	Observed 9 years post operatively. Beginning degenerative joint changes. Whitman operation on right
Drilling (femoral neck and subtrochanteric osteotomy)	5	Unilateral	Good	Two stage operation. Follow-up 3 years
	15½	Bilateral (left)*	Good	One stage operation. Follow-up 4 years
	9	Bilateral	Fair	One stage operation, with removal great trochanter. Follow-up 3 years
	15½	Unilateral	Poor	Required second osteotomy with good correction. One stage
	7	Bilateral (left)*	Poor	Partial ankylosis of hip joint. One stage
	5	Unilateral	Poor	Two stage operation. Loss of control of fragments and abduction contracture of hip joint
	14	Unilateral	Poor	Follow-up 8 years. Fair but hip due to degenerative arthritis
Bone graft and subtrochanteric osteotomy		Unilateral	Poor	Required second osteotomy. No follow-up
Bone peg with reposition of femoral head	7	Bilateral	Poor	Left side only. Postoperative infection resulted in ankylosis of both hip joints
Bone peg through head and downward shift of great trochanter	7	Unilateral	Poor	Ankylosis of hip joint with flexion-adduction deformity
Whitman operation	5	Bilateral (rt.)*	Poor	Follow-up 5 years. Pain and disability
Resection of portion of epiphyseal plate	6	Unilateral	Unknown	Epiphyseal dysplasia. Fusion obtained. Did not return for subsequent osteotomy

*Bilateral cases with different operations on each side

Subtrochanteric osteotomy On theoretical grounds a postoperative recurrence of coxa vara deformity might be anticipated in a young patient whose roentgenograms demon-

strate a highly disorganized epiphysal plate and femoral neck at the time of osteotomy because of progressive activity of this underlying lesion. Recurrence of varus deformity was observed in this study in 4 patients whose ages ranged from $5\frac{1}{2}$ to 7 years. However this complication was observed immediately or shortly after operation in all instances and was due to inadequate or improper control of the postosteotomy fragments. Indeed the fact that progression of varus deformity did not occur in the femoral neck once union occurred following subtrochanteric osteotomy, and that the epiphysal plate regions appeared to mature spontaneously in these cases lends support to those who advocate subtrochanteric osteotomy alone without supplemental drilling of the femoral neck in the treatment of congenital coxa vara.

Recurrence of the varus deformity immediately following subtrochanteric osteotomy is due to certain mechanical difficulties encountered in the control of the postosteotomy fragments. When a subtrochanteric or intertrochanteric osteotomy is performed in the presence of an ankylosed hip joint, the position of the femoral fragments is easily controlled by adequate external fixation (plaster of paris) because the short proximal fragment is fixed. When such an osteotomy is done in the presence of a movable hip joint it may be difficult to control the proximal fragment the head and neck rotating as the distal fragment is abducted (8). This difficulty prevails whether the osteotomy is transverse or oblique with or without excision of a lateral wedge of bone or is curvilinear V, L- or Z-shaped, procedures designed to prevent displacement of the osteotomy fragments. Furthermore in order to correct a varus deformity of 90 degrees or less the thigh would have to be abducted to a position in relation to the fixed pelvis which is impossible except in very young infants because of the restricting ligaments and adductor muscles, unless so much bone is sacrificed as to jeopardize control of the femoral fragments and to encourage increased shortening (9).

To obviate these difficulties the long axis of the proximal femoral fragment should be maintained in its proper relation to the pelvis

leaving the abnormal relation of the femoral shaft to the neck to be corrected by bringing the major distal fragment into the necessary degree of abduction. Control of the proximal femoral fragment may be secured by the use of a stainless steel pin incorporated in the plaster of paris encasement or stainless steel pins or Schanz screws in both fragments may be fixed to each other by a Riedel plate or some modification thereof and incorporated in the plaster encasement (9). On the other hand the femoral fragments may be fixed to each other internally by the use of a Blount or Moore type of metal plate (1). A well-leg traction apparatus may be used after osteotomy to control the distal fragment by traction in cases in which the hip joint is mobile and particularly where the contracted soft tissues and muscle spasm prevent immediate correction of the deformity (8, 11).

Drilling of or implantation of a bone peg through the femoral neck. The rationale of drilling the femoral neck or introducing a bone graft through it into the head as measures to revascularize and revivify bone as recommended for example, in the treatment of degenerative arthritis of the hip joint, has not been sustained by clinical experience (6) or by the writer's histologic studies. Histologic sections from the femoral head in several cases of degenerative arthritis of the hip joint and of Perthes disease treated by multiple drillings indicate that these drill holes persist for years, become filled with connective tissue, and in no way modify the progress of these disease processes. Nor is it clear how a piece of transplanted bone, avascular in itself will aid in the process of revascularization.

Treatment of secondary severe degenerative arthritis of the hip joint. Cases with severe coxa vara of long duration pose the additional problem that a good surgical correction of this deformity may fail to effect a satisfactory functional result in the presence of secondary degenerative changes in the femoral head and hip joint. The use of arthrodesis in unilateral cases and of vitallium cup arthroplasty or resection of the femoral head in bilateral cases as discussed by the writer for the treatment of degenerative arthritis of the hip joint (7) would appear to apply also to the late cases.

CONCLUSIONS

1 This investigation is based on 17 cases of congenital or developmental coxa vara. This deformity should be suspected in any child who manifests a painless limp. Pain which appears in adolescence and in the adult is appears on the degree of deformity and shortening, and upon the extent of degenerative changes which affect the hip joint largely on a static basis. The roentgenograms and histologic studies in these cases show a pronounced disorganization of the femoral neck in the region of, and distal to the epiphyseal plate, the exact nature of which is not clearly understood.

2 An evaluation of the results of surgery in these 17 cases of congenital or developmental coxa vara fails to justify the use of drill ing of, or introduction of a bone graft through the femoral neck as a procedure supplemental to corrective osteotomy. The results have been satisfactory more consistently with a lesser incidence of immediate postoperative complications, following simple subtrochanteric osteotomy than by any other method. Recurrence of coxa vara deformity after subtrochanteric or intertrochanteric osteotomy in 4 cases was due to mechanical difficulties involving control of the postosteotomy fragments, particularly in the presence of a movable

hip joint. A good surgical correction may be initiated in cases in which the coxa vara deformity has been of long duration and the follow up period sufficiently long, as a result of the appearance of secondary degenerative changes in the femoral head and hip joint.

THE EFFECT OF TETRA-ETHYL AMMONIUM CHLORIDE ON GASTRIC SECRETION AND ACIDITY IN PEPTIC ULCER

JOSÉ M. FERRER, Jr., M D New York, New York

THE excessive secretion of acid gastric juice at night when the stomach is empty of food has been shown by Dragstedt to be a major contributing factor in the origin and particularly in the continuing activity of peptic ulcers. He has further shown that the amount of free stomach acid and the volume of the night gastric secretion are excessive in patients with peptic ulcer as compared with normal persons or patients with other diseases. To decrease this night secretion Dragstedt (4 5 6) devised an efficient method of sectioning the vagus nerves to the stomach. This operation has proved to be effective in its purpose. Following complete section of both vagus nerves a marked decrease in the secretion of acid gastric juice has been uniformly observed. Unfortunately however the effects of vagus section have not been entirely beneficial. Grimson (9) Moore (8) Walters (10) and other experienced observers have reported postoperative gastric atony dysphagia bouts of diarrhea, and certain other unpleasant gastrointestinal manifestations.

Because of these unfortunate effects of vagus section it occurred to the author that a method of temporary vagal block might effectively decrease the excessive night gastric secretion in the patient with peptic ulcer without interfering with vagal function during the day when acid gastric juice and peristaltic activity are needed in the processes of digestion.

The published investigations of Acheson Moe Lyons and their co-workers (1 2 3 7) indicate that tetra-ethyl ammonium salts produce an effective block of all autonomic nerve impulses, both sympathetic and parasympathetic, and that this block occurs at the auto-

nomic ganglia. One of the many effects of this block is reported to be a decrease in gastrointestinal motility and in the volume and acidity of the gastric juice.

With these preliminary thoughts, an investigation was undertaken to determine whether the excessive night secretion in patients with peptic ulcer could be prevented by vagus nerve block with tetra-ethyl ammonium chloride (etamon). In evaluating the results of this investigation it must be kept in mind that the block produced by etamon is not a pure vagal block but a combination of vagal plus sympathetic block.

Sixteen patients with peptic ulcers proved by x ray examination or gastroscopy were selected at random from the hospital wards. Eleven of these patients had duodenal ulcers, 3 had marginal ulcers at the sites of previous gastroenterostomies, 1 had a gastric ulcer and 1 had multiple gastric ulcers. One of the patients with duodenal ulcer was tested twice (No. 10 in Table I) and he subsequently proved at operation to have a giant follicular lymphosarcoma of the stomach in addition to a duodenal ulcer. In the cases of marginal ulcer the measurement of the 12 hour secretion is less reliable because of the presence in each of these cases of a gastroenterostomy.

The following schedule was carried out on each patient.

The usual hospital supper was given at 5:00 p.m. Nothing by mouth was allowed thereafter until the completion of the gastric drainage on the following morning. At 8:30 p.m. a gastric lavage was done through a large caliber tube until the return was clear. Continuous nasogastric suction was then carried out from 9:00 p.m. to 9:00 a.m. The total 12 hour volume of the suction drainage was measured and determinations of the free and total acidity were made.

On the succeeding night the same procedure was repeated with the added factor of intra-

TABLE I—TWELVE HOUR NIGHT GASTRIC SECRETION AND ACIDITY

Patient	Intramuscular etamon dosage		Without etamon			With etamon		
			Volume in c.c.	Units of free acid	Units of total acid	Volume in c.c.	Units of free acid	Units of total acid
	Mgms of etamon per kg of body weight	Interval of administration	690	75	3	900	90	90
	30 g	One dose	(Five hour secretion)			(Five hour secretion)		
1. K.H.		Every 6 hours		18	02	270	24	46
2. L.P.	8.0	Every 6 hours	1026	9	24	2000	3	18
3. E.L.	19.0	Every 6 hours	364	6	3	50		90
4. D.R.	30	Every 6 hours	150	20	43	0		11
5. J.M.	30	Every 6 hours	473		3	150	19	43
6. C.T.	30.6	Every 6 hours	190		3	460	43	79
7. G.L.		Every 6 hours	500	73	107	690	47	106
8. N.A.	21	Every 6 hours	1000	15	60	590	0	34
9. L.H.	5	Every 6 hours	545	30	85	160	5	37
10. E.T.	7.0	Every 4 hours	600	4	40	400	0	30
	17.0	Every 4 hours	573	10	90	680		23
11. H.J.	8	Every 4 hours	1000	5	40	5	1	44
12. A.M.	12.0	Every 4 hours	1450	30	53	400	20	61
13. M.G.	9	Every 4 hours	550	3	53	345	8	87
14. K.B.	0.1	Every 4 hours	740		5	43	13	31
15. A.L.	0.5	Every 4 hours	93	16				
6. A.S.	30 g	Every 4 hours						

muscular etamon The doses of etamon varied from 17.9 to 21.6 milligrams per kilogram of patient's body weight. The doses were given at 6 hour intervals (at 9:00 p.m. and 3:00 a.m.) in 8 patients, and at 4 hour intervals (at 9:00 p.m., 1:00 a.m., and 5:00 a.m.) in 6 patients. One patient was tested twice once at 6 hour intervals and once at 4 hour intervals. The first patient was tested for 1 night only drainage being obtained for 5 hours without etamon and for 5 additional hours following a single dose of etamon.

The etamon dosage employed and the results of the investigation are shown in Table I.

Very few side effects of etamon were noted—all were transient and none was serious. Among these side effects were blurring of vision in 2 patients, a 'shaky' or 'jumpy' feeling in 1 patient, and a temperature of 101.6 degrees with moderate cellulitis of both buttocks at the injection sites in 1 patient. Blood pressure readings were checked in about half the cases and there was always a drop about 1 hour after each dose of etamon. This drop varied from 7 to 34 points in the systolic pressure and from 2 to 22 points in the diastolic

pressure. This drop was transient and the pressure returned to normal within 3 to 4 hours.

SUMMARY

Effective reduction of the 12 hour night secretion or acidity or both was accomplished in 12 out of 17 gastric drainage tests done with the administration of intramuscular etamon. Two tests failed to effect a significant reduction in either secretion or acidity. 2 other tests resulted in a significant decrease in the volume of secretion but a rise in the levels of both free and total acid while another test showed no change in secretion but a definite decrease in the free and total acidity.

Nine tests were done with etamon given at 6 hour intervals. Of these, 1 did not show a significant decrease in secretion or acidity, 2 showed a decrease in secretion but an increase in acidity and 1 resulted in decreased acidity but an unchanged volume of secretion.

Seven tests were done with etamon dosage at 4 hour intervals, and only 1 failed to show a decrease in secretion or acidity. The diagnosis of marginal ulcer in this last patient was not clear cut.

In 1 case a marked decrease was exhibited in both secretion and acidity for the 5 hours following a single dose of etamon.

The slight variation in the milligram dosage was dictated by the necessity of measuring the dose in cubic centimeters for injection. No difference in results could be attributed to this slight variation which was present in the milligram dosage.

In determining the adequacy of the dosage interval it is of interest that Case 10 was tested twice—once at 4 hour intervals and once at 6 hour intervals. This patient showed a poor response to etamon dosage at 6 hour intervals but a very good response when the dose was repeated at 4 hour intervals.

CONCLUSIONS

1. Tetra-ethyl ammonium chloride (etamon) prevented excessive night gastric secretion and acidity in 12 out of 17 tests of patients with peptic ulcer studied.

2. Intramuscular etamon dosage of approximately 20 milligrams per kilogram of body weight is usually adequate to produce the above effect if repeated at intervals of 4 hours but is not uniformly adequate at intervals of 6 hours.

3. When etamon was given at 4 hour intervals, excessive night gastric secretion and acidity were inhibited in 6 out of 7 patients with peptic ulcer.

4. No serious toxic or side effects of etamon were noted.

5. Transient fall in both systolic and diastolic blood pressures was noted after etamon administration.

6. Therapeutic trial of the effect of etamon on the symptoms and healing of peptic ulcers is warranted and will be undertaken.

TRANSITION OF PANCREATIC EDEMA INTO PANCREATIC NECROSIS

H. L. POPPER, M.D., H. NECHELES M.D. Ph.D., and KEMPER C. RUSSELL, Chicago, Illinois

THE usual pathogenetic mechanism of acute pancreatitis in man is a block at the papilla of Vater in the presence of a common channel between common bile duct and pancreatic duct. This block caused either by stone or by spasm will lead to stagnation of pancreatic juice and of bile in the common channel. The subsequent increase of pressure in the duct system and the intraductal activation of pancreatic juice are considered to be the causes of acute pancreatitis.

The authors have demonstrated the presence of a common channel in 89 per cent of a series of cases of pancreatic edema of acute pancreatitis and of pancreatic necrosis (3). This finding together with the observation that transition of pancreatic edema into acute pancreatitis occurred not so rarely made us feel that basically, these processes were not different. Why, however, in some cases edema of the pancreas would develop and in others hemorrhagic necrosis remained to be answered.

After we had succeeded in producing experimentally an extensive edema of the pancreas under conditions resembling physiologic processes (4) the question arose how this same mechanism would lead to the development of pancreatic necrosis. Our method of producing pancreatic edema consisted in stimulation of external pancreatic secretion by intravenous injection of a large dose of secretin after ligation of the main pancreatic duct or of the main and accessory ducts. Though this procedure rarely failed to produce edema of the pancreas it never caused pancreatic necrosis.

Similar experiments with stronger and more prolonged stimulation of pancreatic secretion by constant intravenous infusion of secretin solution over several hours, or by repeated

administration of large doses of secretin at short intervals over a period of several hours did not lead to pancreatic necrosis.

We had felt heretofore, that pancreatic edema and acute pancreatitis were probably different reactions to or different degrees of the same process. However, the observation that secretin produced edema only and never produced pancreatitis suggested that an additional factor was necessary to transform pancreatic edema into pancreatitis or pancreatic necrosis.

The following procedures designed to transform pancreatic edema into pancreatic necrosis, gave negative results. Ligation of the cysterna chyli in order to block lymphatic drainage from the pancreas, temporary clamping of the portal vein, shock produced by trypsin or by gross trauma. However temporary occlusion of the main pancreatic (gastroduodenal) artery performed in animals with edema of the pancreas, led to the development of pancreatitis. In order to make sure that this occlusion of the pancreatic artery by itself would not cause necrosis of the pancreas preliminary control experiments were performed which showed that this procedure applied for 30 to 45 minutes in a normal dog was not followed by gross or microscopic changes of the pancreas.

METHODS

Seventeen healthy mongrel dogs of both sexes, weighing between 9 and 13 kilograms were used. The animals were anesthetized with pentobarbital sodium and aseptic technique was used throughout operation. In 10 dogs edema of the pancreas developed following secretin injection and the main pancreatic artery was occluded for 15 minutes. The remaining 7 dogs served as controls: (a) without pancreatic edema arterial occlusion was performed after ligation of the pancreatic duct or after injection of secretin, (b) with pancre-

TRANSITION OF PANCREATIC EDEMA INTO PANCREATIC NECROSIS

H. L. POPPER, M D., H. NECHELES M D Ph D and KEMPER C RUSSELL, Chicago Illinois

THE usual pathogenetic mechanism of acute pancreatitis in man is a block at the papilla of Vater in the presence of a common channel between common bile duct and pancreatic duct. This block, caused either by stone or by spasm will lead to stagnation of pancreatic juice and of bile in the common channel. The subsequent increase of pressure in the duct system and the intraductal activation of pancreatic juice are considered to be the causes of acute pancreatitis.

The authors have demonstrated the presence of a common channel in 89 per cent of a series of cases of pancreatic edema of acute pancreatitis and of pancreatic necrosis (3). This finding together with the observation that transition of pancreatic edema into acute pancreatitis occurred not so rarely made us feel that basically, these processes were not different. Why, however in some cases edema of the pancreas would develop and in others hemorrhagic necrosis, remained to be answered.

After we had succeeded in producing experimentally an extensive edema of the pancreas under conditions resembling physiologic processes (4), the question arose how this same mechanism would lead to the development of pancreatic necrosis. Our method of producing pancreatic edema consisted in stimulation of external pancreatic secretion by intravenous injection of a large dose of secretin after ligation of the main pancreatic duct or of the main and accessory ducts. Though this procedure rarely failed to produce edema of the pancreas it never caused pancreatic necrosis.

Similar experiments with stronger and more prolonged stimulation of pancreatic secretion by constant intravenous infusion of secretin solution over several hours or by repeated

administration of large doses of secretin at short intervals over a period of several hours did not lead to pancreatic necrosis.

We had felt heretofore, that pancreatic edema and acute pancreatitis were probably different reactions to or different degrees of the same process. However, the observation that secretin produced edema only and never produced pancreatitis suggested that an additional factor was necessary to transform pancreatic edema into pancreatitis or pancreatic necrosis.

The following procedures designed to transform pancreatic edema into pancreatic necrosis gave negative results. Ligation of the cysterna chyli in order to block lymphatic drainage from the pancreas, temporary clamping of the portal vein, shock produced by trypsin or by gross trauma. However temporary occlusion of the main pancreatic (gastroduodenal) artery, performed in animals with edema of the pancreas, led to the development of pancreatitis. In order to make sure that this occlusion of the pancreatic artery by itself would not cause necrosis of the pancreas preliminary control experiments were performed which showed that this procedure applied for 30 to 45 minutes in a normal dog was not followed by gross or microscopic changes of the pancreas.

METHODS

Seventeen healthy mongrel dogs of both sexes weighing between 9 and 13 kilograms were used. The animals were anesthetized with pentobarbital sodium and aseptic technique was used throughout operation. In 10 dogs edema of the pancreas developed following secretin injection and the main pancreatic artery was occluded for 15 minutes. The remaining 7 dogs served as controls (a) without pancreatic edema arterial occlusion was performed after ligation of the pancreatic duct or after injection of secretin (b) with pancre-

7	+	+	+		8		

Edema: + moderate, ++ marked, +++ very marked

atic edema, but without occlusion of the artery

Secretin was injected intravenously at a slow rate in two doses of 30 milligrams each given at a 5 minute interval. The ligation of the pancreatic duct was done with care so as not to traumatize the pancreas. We found that the main pancreatic artery could be exposed and clamped easily where it branches from the hepatic artery and runs straight caudad in the gastrohepatic ligament. The artery was occluded with a soft rubber-covered bulldog clamp for 15 minutes and after removing the clamp we ascertained by palpation and inspection that circulation in the distal portion of the artery was normal again. The animals, with the exception of 3 that died after the operation were sacrificed between the 2nd and 8th postoperative days.

The results are presented in Table I which contains the control experiments and in Table II which shows the results in the 10 dogs in which temporary occlusion of the pancreatic artery was performed in the presence of edema of the pancreas.

Dogs 1, 2 and 3 (Table I) developed an extensive edema of the pancreas following ligation of the main pancreatic duct and subsequent injection of secretin. No arterial occlusion was performed. The animals were sacrificed on the 3rd, 5th and 6th postoperative days, respectively and autopsy showed some induration of the pancreas in 1 of the dogs, but otherwise no gross and no microscopic changes of the pancreas. In dogs 4 and 5 the main pancreatic duct was ligated but no secretin was given and no edema appeared.

Subsequently the pancreatic artery was clamped for 15 minutes. These dogs were sacrificed on the 3rd and 6th postoperative days respectively. One of these dogs showed grossly an indurated pancreas, the other showed only microscopic signs of a beginning cirrhosis of the pancreas. Dog 6 received secretin injection without previous duct ligation and no edema developed. Five minutes after the termination of the secretin injection the pancreatic artery was clamped. The dog was sacrificed on the 5th postoperative day; autopsy revealed no gross abdominal pathology and no microscopic changes in the pancreas. Dog 7 received secretin after ligation of the main pancreatic duct but no edema developed. Five minutes after the termination of the secretin injection the pancreatic artery was clamped for 15 minutes. The dog was killed 8 days later. Autopsy revealed no gross abdominal pathology and no gross changes in the pancreas. Microscopic examination of several sections of the pancreas revealed a normal gland.

In Table II the results are tabulated according to the degree of pancreatic edema present just before occlusion. In experiments 8 and 9, without ligation of pancreatic ducts, a low grade edema appeared after secretin injection. Dogs 10 to 16 had the ducts ligated and developed pancreatic edema after injection of secretin. In 4 of these dogs only a moderate degree of edema appeared because relatively small doses of secretin had been administered to 2 dogs and a preparation of secretin of low potency had been given to the other 2 dogs.

*Edema (+) slight; ++ moderate; +++ marked; ++++ very marked

oSingle dose of 15 mgm. secretin.

The 3 remaining dogs showed very extensive edema. Dog 17 developed very marked edema of the pancreas shortly after ligation of the main and accessory pancreatic ducts and therefore temporary arterial block was performed without injection of secretin. Dogs 9 and 11 died of pneumonitis on the 2nd and 4th postoperative days respectively, and dog 15 died of pancreatitis and peritonitis on the 2nd postoperative day.

Table II shows, in contrast to Table I, that in every dog some degree of pancreatitis and of fat necrosis existed. The 6 dogs (8 to 13) that had only low grade edema of the pancreas at the time of the arterial occlusion did not show marked generalized changes of the pancreas but 4 of these dogs had bloody intra-peritoneal fluid and all of these animals had fat necroses around the pancreas and in the omentum. Microscopic examination revealed fat necroses in all of these animals and small areas of glandular necrosis in the pancreas of dogs 8 and 11.

All dogs with extensive pancreatic edema at the time of arterial occlusion revealed pronounced changes. Dog 16 had large numbers of fat necroses in the omentum and around the pancreas and sections revealed extensive areas of fat necrosis in the pancreas and in the peripancreatic fat tissue. The 3 other dogs showed changes that looked like pancreatic necrosis or hemorrhagic pancreatitis with diffuse fat necrosis which on microscopic examination proved to be hemorrhagic and necrotizing pancreatitis with extensive fat necrosis.

COMMENT

Since we did not succeed in producing pancreatic necrosis by increasing or prolonging the edema producing administration of secretin it became apparent that pancreatic necrosis or hemorrhagic pancreatitis is not merely an advanced form or a later stage of pancreatic edema. It seemed probable that an additional factor was responsible. This additional factor was not added by such procedures as obstruc-

tion of lymphatic drainage obstruction of venous return from an edematous pancreas or the production of shock in dogs with edema of the pancreas. However positive results were obtained with the temporary occlusion of the main pancreatic artery if performed while edema of the pancreas was present. If no edema of the pancreas was present clamping of the pancreatic artery did not produce pancreatitis. When pancreatic edema was present, clamping of the artery caused pathologic changes in and around the pancreas that were in direct proportion to the degree of the edema, whether the edema was caused by injection of secretin or had developed spontaneously. In case of low grade edema only fat necroses developed but in cases with extensive edema all the changes were found that severe forms of pancreatitis can reveal.

We have shown in previous experiments (4) that edema of the pancreas can be produced by vigorous stimulation of the external pancreatic secretion by secretin injection after the main pancreatic duct has been ligated and we have shown (2) that the intrapancreatic and peripancreatic edema consists of pancreatic juice that has diffused into the connective tissue of the gland. The edema will do little or no damage to the pancreatic gland and will disappear shortly after the secretory stimulus has been discontinued, leaving few or no traces. This process seems to be identical with the clinical picture of transient pancreatitis.

However when the arterial supply of the pancreas is interrupted in the presence of pancreatic edema changes will develop that range from mild forms of intrapancreatic fat necrosis to severe hemorrhagic and necrotizing pancreatitis. The temporary ischemia probably lowers the resistance of the cells to the enzymatic action of the edema fluid but it is possible that the pancreatic enzymes of the edema fluid might be activated by contact with unpaired cells.

Whatever the explanation may be the important fact is that temporary local ischemia is able to transform a clinically harmless transient edema of the pancreas into a hemorrhagic pancreatic necrosis.

The clinical applications of these experimental observations are

1. Local vasomotor changes may be responsible for the transition of pancreatic edema into pancreatic necrosis.

2. The extent of local vasomotor changes may determine the degree of pancreatitis.

3. If acute pancreatitis is diagnosed or its presence is suspected everything should be done to make a presumably present edema disappear and to avoid local ischemia.

To make the edema disappear it seems best to give spasmolytics which will relax the sphincter of Oddi to prevent any stimulation of the external secretion of the pancreas, and to attempt its active inhibition. There is little we can do to prevent local ischemia except to prevent shock and to avoid medication that has a vasoconstrictor effect in the splanchnic area. Administration of papaverine with its vasodilating action may be of value.

Local vasomotor changes are nothing unusual after surgical procedures and this may in part explain the poor results of surgical intervention in acute pancreatitis.

In previous publications (1) impressive therapeutic results were reported with paravertebral block in acute pancreatitis. In the light of the recent experiments it seems suggestive to ascribe these good results partly to local vasodilation produced by blocking the sympathetic innervation to the pancreas.

SUMMARY

Experiments prove that pancreatic edema and acute pancreatitis or pancreatic necrosis are not merely different degrees of the same process but that another pathogenetic factor is necessary to transform one into the other.

In animal experiments transformation of pancreatic edema into pancreatitis or pancreatic necrosis was attained by temporary occlusion of the main pancreatic artery.

The important part which local vasospasm and ischemia may play in the development of clinical cases of acute pancreatitis is discussed and therapeutic measures are recommended.

SELF CENTERING LORENZ OSTEOTOMY

CARLO SCUDERI M.D., Ph D., Chicago Illinois

THE Lorenz osteotomy has proved one of the most effective methods of treating nonunion of fractures of the neck of the femur especially in the case of elderly people who could not tolerate some of the more extensive operative interventions.

Careful analysis of a relatively large number of such operations, performed during the last 9 years, has shown that the most common cause of failure has been the displacement of the shaft of the femur either anteriorly or posteriorly to the stump of the neck and head against which the shaft must impinge for stability on weight bearing. The "self centering" Lorenz osteotomy has been devised to minimize this danger.

The principle of the self centering osteotomy is the "V" cutting of the femur at just above the superior border of the lesser trochanter.

From the Fracture Service, Cook County Hospital.

Fig 1

Fig 1 It is desired that the osteotomy be done just above the superior margin of the lesser trochanter. For this reason a Kirschner wire should be placed, under x-ray control, at the desired angle and location for the osteotomy.

Fig 2 In the original Lorenz osteotomy a transverse cut was made as illustrated in Figure A, with a resulting possibility of the shaft gravitating either forward or backward from the desired central position as illustrated in Figure B.

Fig 3. By producing a forked osteotomy Figure A, the shaft tends to seek and maintain a central position

chanter so that a trough is made from the lateral to the medial aspect of the femur with the central portion of the "V" about $\frac{1}{2}$ inch lower than the sides. The "V" cut then tends to center the shaft of the femur under the head, and there is far less tendency for it to gravitate either anteriorly or posteriorly to the desired position. As is already well known to those who have done the Lorenz osteotomy the shaft must be pushed medially so that it comes to rest directly under the head.

The direct lateral approach has the advantage of less surgical trauma and of speed of procedure. When excellent x ray facilities are available for control, this approach is the preferred method especially in thin people. When x ray facilities are not available, and in obese women it has been the author's experience that the "hockey stick" incision with cutting of the fascia lata at the inferior portion of the

Fig 2

Fig 3

under the head and neck, Figure B because of the slanting sides of the osteotomy which constantly tend to "self center" the shaft of the femur. The anteroposterior position of the resulting osteotomy should be as shown in Figure C.

incision and muscle plane dissection between the rectus femoris and extensor fascia femoris, has been more advantageous. By opening the capsule through a longitudinal incision direct visual control is possible of the fracture site, the location of the osteotomy and the final position of the shaft of the femur under the neck of the femur.

In doing the osteotomy a longitudinal muscle splitting of the vastus lateralis can be carried out and the lateral aspect of the femur exposed. In the author's experience this procedure has been most advantageous, as it can be rapidly done and the occasional bleeder can be readily isolated and ligated. Others prefer to locate the posterior margin of the vastus lateralis and reflect the entire muscle anteriorly thereby exposing the femur at the desired level for the osteotomy. Either method is satisfactory.

Postoperatively the patient must be placed with the limb operated upon in wide abduction

to maintain the shaft of the femur under the head. A spica cast to the toes on the side operated upon and to the knee on the other side is the best method of immobilization. In the application of the cast, care must be taken that too much strain is not placed on the medial side of the knee joint when abduction of the femur is sought, otherwise an undesirable genu valgus results.

It has been found most advantageous to maintain immobilization in a cast for 8 weeks and then to place the limb in skin traction with five pounds of weight, and each day bring the leg a little more into adduction. When the extremity reaches a parallel position to the long axis of the body the traction is removed and the patient is gotten up on crutches with light weightbearing.

In the average case ambulation with a cane and with minimal discomfort is possible in about 4 to 6 months after operation has been carried out.

FACTORS INFLUENCING MORTALITY FROM ACUTE PERFORATED PEPTIC ULCERS

WILLIAM T. McELHINNEY, M.D., and CHARLES E. HOLZER, Jr., M.D.
Cincinnati, Ohio

ALTHOUGH considerable strides have been made in the treatment of perforated peptic ulcer since the first successful closure reported in 1892 by Heussner, this condition remains one of the most serious of the common emergencies of abdominal surgery. Recent reports indicate a marked reduction in operative mortality rates from the series reported in 1940 by DeBakey with 18.2 per cent mortality, to the more recent figures of Graham, 6.4 per cent; Fallis, 8.3 per cent, and Bantell, 1.1 per cent.

Our mortality statistics are not presented as representing the ultimate goal of therapy. Most of our group of patients are from the lower strata of society and enter the hospital in poor nutritional and physical condition. This type of patient taxes therapeutic measures to the utmost.

The present study comprises 336 cases of acute perforated peptic ulcer seen at the Cincinnati General Hospital during the 12 year period 1935-1946 inclusive, and treated by the resident surgical staff (Fig. 1). In routine care at this clinic simple closure of the ulcer, closure of the abdomen with wire, and careful pre-operative and postoperative control of fluid balance have been emphasized. The general mortality by 3 year periods has shown a progressive decline from 31 per cent in the period 1935-1937 to 11 per cent for the period 1944-1946. The operative mortality has been reduced from 21 per cent to 10.7 per cent in the same time (Fig. 2).

One of the most important factors affecting the operative mortality in perforated ulcer is the time elapsing before closure of the perforation (Table I). Comparison of our series with that of DeBakey shows that 87.9 per cent of

our patients were operated upon within the first 12 hours as compared with 81.85 of his cases. DeBakey reported that the mortality rate increased from 14.6 per cent in patients operated upon within the first 12 hours to 42.6 per cent of those in the 12 to 24 hour group and reached 61.5 per cent in patients in whom over 24 hours had elapsed. Our mortality statistics for the period 1935 to 1941 are substantially the same as DeBakey's, but in the last 3 year period (1944-1946) we have experienced a drop to 6.4 per cent mortality among patients undergoing operation within the first 12 hours.

The age of the patient also markedly influences the mortality rate (Fig. 3). More than three times as many deaths occur in the 50 to 59 year age group as in the 20 to 29 year old group. Comparison of our series with that of DeBakey shows a striking similarity in the mortality curve, deviating only at the 70 to 79 year group. Tabulation reveals that 41.5 per cent or less than half of our patients have been under 40 years of age, as compared with 55.1 per cent of DeBakey's series (Fig. 4). We have further noted in comparing our patients of the 20 to 29 year age group with the patients over 50 that 22.5 per cent of the older group were seen more than 24 hours after perforation while in the younger group only 4.5 per cent entered the hospital after 24 hours had elapsed. In our cases the diagnosis has been more often missed or delayed in the older patients since many of this group enter the hospital late in the course of their illness.

Three adjuvants to routine treatment have been added in the 12 year period covered by this study. These have been (1) the use of continuous gastric suction, (2) the use of spinal anesthesia, and (3) the introduction of chemotherapy (Fig. 5). Wangensteen suction drainage was introduced in 1935, and since 1938 has been used in 100 per cent of the cases. Spinal

From the Department of Surgery, College of Medicine of the University of Cincinnati, and the Cincinnati General Hospital. Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, September 8-11, 1947.

Fig. 1. Number of cases seen per year in period 1935-1946, of total of 336 cases at Cincinnati General Hospital.

anesthesia was also introduced in 1935 and has been employed in varying numbers of cases throughout the 12 year period. We have not been able to demonstrate that the use of spinal anesthesia directly affects the mortality rate nor that respiratory complications have increased or lessened because of its use.

Administration of sulfonamides was begun in 1938 and was gradually increased until 100 per cent of patients with perforated ulcer were receiving this therapy by 1945. In 1945 penicillin was given to 50 per cent of the cases; by 1946 all patients received penicillin and 50 per cent were given sulfadiazine in addition.

The value of chemotherapy in decreasing the incidence of wound infection and subphrenic abscess is clearly demonstrable. Wound infection which had occurred as frequently as in 30 per cent of the cases (Fig. 6) was reduced to 10 per cent when half of the patients oper-

Fig. 2. Comparison of general and operative mortality rates by 3 year periods, 336 cases seen at Cincinnati General Hospital from 1935 through 1946.

ated upon received penicillin and was completely eliminated with routine administration of penicillin. The most striking results have been obtained in the group of patients undergoing operation within the first 6 hours after perforation and given chemotherapy. There have been no deaths in this group in the last 3 year period. In the group operated upon within 7 to 12 hours after perforation and given chemotherapy mortality has been reduced from 21.6 per cent to 10 per cent since the use of sulfonamides, and to 7.7 per cent with the introduction of penicillin. Subphrenic abscess has occurred in 11 patients following closure of gastroduodenal perforation. Eight of these developed subphrenic abscess despite the fact that they were receiving sulfonamide therapy. Since the use of penicillin there has been no incidence of subphrenic abscess. Analysis of the 73 deaths (Fig. 7) revealed that generalized peritonitis was the cause of death in 46.6 per cent. Shock and respiratory complications each caused 13.3 per cent of the deaths and cardiac difficulty was responsible in 10.6 per cent. Since peritonitis was determined to be the cause of death over 3 times as often as any other single cause, we believe that the bacterial element in perforated ulcer is a most important factor.

TABLE I—PERFORATED PEPTIC ULCER—306 PATIENTS OPERATED UPON AT CINCINNATI GENERAL HOSPITAL, 1935-1946

Hours elapsed before closure comparison with DeBakey

Hours	Number of cases	Per cent	DeBakey
1 to 6	14	4.6	30.8
6 to 12	25	8.2	3
12 to 24	5	1.6	0.1
24 to 48	3	0.9	0.3
Over 48	1	0.3	1.6
Total cases	306		

Fig 3 Mortality rate according to age comparison with DeBakey

Fig 4 Age incidence compared with series reported by DeBakey

Eighty-seven per cent of the patients seen gave a history of previous epigastric distress. Seventy per cent of those with epigastric symptoms gave a history of over 6 months duration. In our study there were 10 perforations, an incidence of 2.9 per cent. Nine of these were seen in the first 6 hours. One re-perforation was fatal.

Thirteen cases were not recognized as perforated ulcer on admission of patient to the hospital and diagnosis was made on the medical or the psychiatric services. Twelve of these had had ulcer perforated for longer than 24 hours. In 45 per cent of the cases positive

diagnosis could not be made. One of the causes for delaying diagnosis was gradual onset of symptoms. Five per cent of our patients had a gradual onset of abdominal pain. In an additional 5 per cent, abdominal pain was noted to occur most markedly in the right lower quadrant.

Vomiting occurred in 47 per cent of the series following perforation, 24 per cent experienced vomiting one time and 23 per cent vomited more than once. It has often been said that patients with perforated ulcers do not vomit. This has not been true of almost one half of our cases. It seems likely that the

Fig. 5. Percentage of cases receiving Wangensteen suction drainage, spinal anesthesia, sulfonamide drugs, and penicillin.

amount of material in the stomach at the time of perforation determines the amount of vomiting.

Graham found that the white count is usually elevated and in his series there was only one instance in which the white count was below 5,000. In 4 per cent of our series the white count was below 4,000; in 27 per cent it was between 5,000 and 10,000; in 33 per cent between 10,000 and 15,000; and in 35 per cent above 15,000. Sixty per cent of our cases had a white count of more than 10,000. Temperature on admission to the hospital was less than 99 in 53 per cent of the cases; in 25 per cent it was between 99 and 100; and in 22 per cent it was over 100.

Free air in the peritoneal cavity was demonstrated roentgenologically in 66 per cent of the cases. Abdominal findings were described as board-like or markedly spastic in 68 per cent of the cases. Nineteen per cent had increased abdominal spasm and distention was not uncommonly seen in cases in which perforation had been present over 24 hours. Hypoactive

peristalsis was recorded in only 12 per cent of the cases.

The location of perforation was near the outlet of the stomach in 84.7 per cent of the cases (duodenal 56.8 per cent and pyloric 27.9 per cent). Five and three-tenths per cent were gastric and an additional 2.4 per cent occurred on the posterior surface of the stomach. In the remaining 8.6 per cent the location was not reported. The most frequent location of perforation, i.e. near the pylorus, had apparently not been realized by all of the operators, judging by the length of some incisions. Shorter incisions in certain instances might have reduced the incidence of wound infection and evisceration.

Simple closure of the ulcer consisted of laying three or four Lambert sutures of silk through the ulcer bed, closing the ulcer and placing a tag of omentum in the long ends of the sutures and tying it down over the suture line. In cases in which the ulcer could not be easily closed a fold of stomach has been drawn down over the perforation. No cases of py

Fig. 6. Incidence of subphrenic abscess and wound infection.

long stenosis were noted. Two cases of duodenal fistula, one of which communicated with a subphrenic abscess were encountered.

Wound closure was carried out by through and through silver wire plus catgut in the peritoneum and fascia in 60 per cent of the cases. Thirty per cent were closed with through and through silver or steel wire with no peritoneal closure. Four per cent were closed in layers with catgut with silkworm gut stays and 4 per cent were closed in layers with silk.

Wound eversion has been the chief incentive for wire closure. In 8 instances eversion requiring secondary closure occurred. Silver wire had been used in 5 of these. Three eversions were associated with coughing and in each instance the wires broke. The cause was attributed to finer grades of silver wire being used at that time than is ordinarily recommended and steel wires have been more extensively adopted since. Eversion occurred in one individual in whom the peritoneum had been closed in addition to the silver wires. In the other case omentum herniated between the wires. In 2 cases in which closure had been made with catgut and silkworm gut stays the sutures broke. In the eighth case closure had been made in layers with silk. Three patients died after eversion.

In the last 6 years positive cultures were obtained at operation in 29.8 per cent of the cases. In one-fourth of this group the outcome was fatal. On the other hand seven-eighths of all fatal cases for this period had had positive cultures at operation. Other writers have reported an incidence of positive cultures at operation varying between 0 and 93 per cent. Briff reported 74 per cent positive cultures in cases undergoing operation within 6 to 12 hours, and 93 per cent in cases in the group over 12 hours. The fact that an average of 23 per cent of cases in this series developed wound infection prior to the use of penicillin although positive peritoneal cultures were obtained in only 29.8 per cent of the cases indicates that the organisms are of a very virulent nature or that our present culture methods are not adequate. Analysis of culture reports reveals that 49 per cent of the positive cultures contained more than one organism. *Streptococcus* was found in 75.47 per cent of the cultures, 23 per cent of these were of the hemolytic type. *Staphylococcus* was found in 32 per cent. *Bacillus coli* in 18.8 per cent, and *Aerobacter aerogenes* in 15 per cent.

Shock associated with acute perforated ulcers has been a subject of considerable discussion. Soutter studying 335 cases found pro-

Fig. 7 Cause of death—73 cases.

found shock in only 3 instances and mild shock in 6 per cent. He attributed early shock to associated hemorrhage and late shock to peritonitis. Graham emphasized the nutritional and biochemical imbalance associated with shock as being responsible for the serious state of these patients. Blood pressure has been selected as the most constant single criterion of shock. In this series there were 25 patients or 7.4 per cent with blood pressure below 100 millimeters systolic on admission. In 14 or over half of these the ulcer had been perforated less than 12 hours. Three of the patients with perforation of less than 12 hours duration succumbed to shock and were not operated upon. One of these patients was a female, age 52 with a previously perforated gastric ulcer who was in shock on admission 4 hours after perforation. She had associated gastric hemorrhage and expired. The 2 other cases were 7 and 12 hours post perforation respectively. There was no evidence of gastrointestinal hemorrhage but in spite of therapy with intravenous blood both expired.

Ten of the patients in shock on admission less than 12 hours after perforation were operated upon with 8 recoveries. None of the 11

patients entering more than 12 hours after perforation with blood pressures under 100 millimeters systolic survived. Five of these underwent operation.

Four cases with adequate blood pressure at time of operation died within 36 hours after operation in shock like condition. They had been closed $2\frac{1}{2}$, $7\frac{1}{2}$, 9 and 17 hours respectively following perforation. Three of these had positive cultures in the peritoneal fluid. In another instance a patient who had an ulcer perforated for $5\frac{1}{2}$ hours was given a spinal anesthetic, following which the blood pressure fell and he succumbed.

There have been 38 patients who had perforations for over 24 hours before admission to the hospital. Fourteen of these who had adequate blood pressures were operated upon. Four survived giving a mortality of 71 per cent. Twenty four patients were treated without operation 16 of whom died a nonoperative mortality of 66 per cent. In our hands nothing has been gained by operation after 24 hours postperforation.

Thirteen of the patients in this study have been women an incidence of 3.8 per cent, as compared with 19 per cent in DeBakey's Charity Hospital series and 7.7 in his collected series. Of the 13 11 were over 40 years of age. Only 6 of the women were admitted in the first 12 hours postperforation. There were 5 deaths, 4 of which followed perforation for over 24 hours. The occurrence of perforation in women near or after the menopause is in keeping with the work of Sandweiss who believes that there is a protective mechanism produced by the ovary and the pituitary gland in younger women which lessens the chance of perforation occurring.

Our therapy although not striking in comparison with the work of others has shown a steady improvement in survival rate in the 12 year period 1935 to 1946. Analysis of the operative deaths for the last 3 years shows that over half of our patients have entered the hospital more than 6 hours after perforation had occurred. In order to give a clearer picture of the type of patient seen at the Cincinnati General Hospital an important influencing factor on our mortality statistics the 9 fatal cases of the last 3 years are briefly summarized.

CASE 7. White female, aged 67 years. This patient was admitted 9 hours after perforation and air was demonstrated under the diaphragm on roentgenological examination. She was treated with 3 units of blood and 2 of plasma. A large perforation of the greater curvature of the stomach was closed under cyclopropane anesthesia 16 hours after perforation. *Streptococcus nonhemolyticus* and *Staphylococcus hemolyticus* were cultured from the peritoneal cavity. Despite administration of 20,000 units of penicillin every 3 hours the patient died within 48 hours. Necropsy revealed (1) acute fibrinous peritonitis and (2) acute lobular pneumonia.

CASE 2. White female aged 76 years. This patient entered the hospital 48 hours after onset of symptoms, and received intravenous fluid therapy for 2½ hours. A small perforation of the anterior duodenum was closed under cyclopropane anesthesia and a peritoneal culture was taken which revealed a yeast. The patient died on the 18th postoperative day. Necropsy showed (1) peritonitis and (2) thrombosis of mesenteric vessels with small and large bowel infarction.

CASE 3. Colored male aged 36 years. This patient had far advanced tuberculosis. A large perforation of the lesser curvature of the stomach was closed 12 hours after its occurrence. Although the patient received penicillin and sulfadiazine his postoperative course was very stormy and he died on the 14th hospital day. Autopsy revealed a perforated duodenal ulcer below the one which had been closed.

CASE 4. Colored male aged 45 years. A large perforation of the pylorus of at least 48 hours duration on admission was closed under local anesthesia despite the low blood pressure of the patient. A streptococcus and *Bacillus coli* were revealed in cultures obtained at operation. Despite supportive therapy including 15,000 units of penicillin every 3 hours 3 units of blood and oxygen by catheter the patient remained confused and disoriented and died within 36 hours.

CASE 5. White male aged 50 years. A small perforation of the anterior duodenum was closed 9½ hours after occurrence under cyclopropane anesthesia. A streptococcus was cultured from the peritoneal cavity. He was given sulfadiazine 5 grams daily until the third day when he received in addition penicillin 20,000 units every 3 hours. He developed delirium tremens on the 4th hospital day, and died on the 5th hospital day of bronchopneumonia.

CASE 6. White male alcoholic, aged 55 years. This patient was admitted to the hospital with a fractured femur. He developed a large anterior duodenal perforation which was closed 17 hours after occurrence. A *Bacillus aerogenes* was cultured from the peritoneum. In spite of two units of blood and two units of plasma this patient went into shock and did not recover.

CASE 7. White female, aged 58 years. This patient entered the hospital 12 hours after onset of symptoms and was given one unit of blood on admission. A large perforation of the pylorus was closed under

local anesthesia 6½ hours later. *Staphylococcus aureus hemolyticus*, *Streptococcus viridans*, and *Streptococcus nonhemolyticus* were cultured from the peritoneum. She received 5 grams of sulfadiazine daily but died on her fourth hospital day. Autopsy revealed generalized peritonitis.

CASE 8. Colored male aged 58 years. This patient entered the hospital 32 hours post perforation. After 4½ hours of therapy including blood transfusion a small anterior duodenal perforation was closed under cyclopropane anesthesia. *Streptococcus viridans* was cultured from the peritoneum. The patient received sulfadiazine 5 grams daily for the first 7 days, and penicillin 20,000 units every 3 hours was added thereafter. He died on his 11th postoperative day. Necropsy revealed generalized peritonitis, subhepatic abscess and pulmonary infarct.

CASE 9. White male aged 33 years. A small perforation of the anterior duodenum was closed under cyclopropane anesthesia 7 hours after duodenal rupture. The patient developed delirium tremens on his second postoperative day. He received 5 grams of sulfadiazine daily for 10 days. He insisted on leaving the hospital on the 14th hospital day while still running a febrile course but soon returned and succumbed on his 62nd postoperative day. Autopsy revealed multiple gastric ulcers, multiple liver abscesses, subhepatic abscess, peritonitis, and portal thrombosis.

SUMMARY

A report of 336 cases of acute gastroduodenal perforation in a large general hospital has been made. The mortality rate has shown a progressive decline from 21 per cent to 10.7 per cent in the 12 year period 1935 to 1946. Under combined penicillin and sulfadiazine therapy the mortality rate has been dropped to 0 per cent in patients treated in the first 6 hours and to 7.5 per cent in patients treated between 6 and 12 hours.

Introduction of chemotherapy with both penicillin and sulfadiazine at the time of diagnosis is advocated since bacterial infection is a most important factor in mortality. Eighty-eight per cent of fatal cases had a positive culture from the peritoneal cavity. There was 25 per cent mortality among patients from whom a positive culture was obtained at operation. Seventy-five per cent of the positive peritoneal cultures contained a streptococcus. Generalized peritonitis was the greatest single cause of death.

Efforts should be directed at early diagnosis especially in women and in older people. In such patients symptoms are not so dramatic

and apparent as in the younger group. Although death from postoperative shock has been rare in our series, it continues to be a factor and all patients should receive adequate preoperative fluids and antishock therapy.

Perforated gastroduodenal ulcers of over 24 hours' duration have done poorly in our hands with or without operation.

CONCLUSIONS

Early diagnosis and prompt surgical intervention with supportive chemotherapy are the

most important factors involved in the successful treatment of acute perforated gastroduodenal ulcer.

INTRAVENOUS, SUBCUTANEOUS AND RAPID INTRAMUSCULAR INFUSIONS OF "PROTEIN HYDROLYSATE"

JACOB JOSEPH WEINSTEIN M D Washington District of Columbia

ARATHER exhaustive investigation of parenteral bovine protein hydrolysate is being conducted. Since the maintenance of protein nutrition in surgical patients requiring parenteral feeding demands intensive therapy with large daily injections, we have attempted to analyze the effectiveness of intravenous, subcutaneous, and rapid intramuscular infusions of this protein hydrolysate. The study represents clinical as well as experimental experiences with parenteral infusions, further, the advantages and difficulties of the routes are discussed.

The major objectives of this study were (1) to determine with intravenous infusions the reaction incidence, the types of reactions, the average amount injected, the average rate of injection, the toxicities, and the local difficulties such as thrombosis, phlebitis, etc., (2) to determine the effect on the blood and urine of infusions of 1000 cubic centimeters of protein hydrolysate in 1 hour (3) to determine the plausibility of repeated subcutaneous infusions of 1000 cubic centimeters of protein hydrolysate in the thighs the effect on the blood on the legs, and the rate of absorption as determined with the use of phenolsulfonphthalein excretion as an indicator, (4) to determine the feasibility of rapid intramuscular injections of 1000 cubic centimeters of protein hydrolysate into the vastus lateralis of the thighs the effect on the blood, on the legs, the reaction of the tissues and the absorption rate as calculated by the use of phenolsulfonphthalein excretion as an indicator.

These studies were all conducted on preoperative and postoperative surgical patients on the wards at the Gallinger Municipal Hospital, Washington, D C. The variables were controlled as well as was possible with the

physical establishment available. All of the infusions and chemical analyses were performed by the author and a technician (George F. Lane).

PREPARATION USED

The solution used in the study is 5 per cent parenteral protein hydrolysate in distilled water. The source of protein is bovine blood and is collected under sanitary conditions, processed, and hydrolyzed by means of a pancreatic enzyme preparation. The hydrolysate is then treated to remove harmful and undesirable constituents and diluted to the desired concentration. Filled sealed bottles of the solution are sterilized by autoclaving and packaged in 500 or 1000 cubic centimeter containers. The finished product is a light amber colored solution containing

Total solids	5.0 grams per 100 c.c.
Total nitrogen	0.55 gram per 100 c.c.
Ammonia nitrogen	0.015 gram per 100 c.c.
Alpha-amino nitrogen	0.575 gram per 100 c.c.
(approximately 50% of the total nitrogen)	
Sodium chloride	0.30 gram per 100 c.c.
	(approximately)
pH.	6.20-6.40

Chemical analyses of protein hydrolysate reveal the following amino acids and their per centages

Arginine	4.91	Lysine	6.10
Aspartic acid	4.56	Methionine	1.06
Cystine	1.15	Phenylalanine	3.30
Glutamic acid	10.34	Threonine	6.00
Histidine	1.93	Tryptophane	1.42
Leucine	7.25	Valine	6.15
Isoleucine	3.94		

Each manufactured lot of protein hydrolysate solution is subjected to control procedures to show that it is sterile, nonpyrogenic, free of vasomotor substances, free of unhydrolyzed protein, and that it may serve as an adequate source of parenteral nitrogen.

METHODS

1. Twenty four hour urine specimens were collected in receptacles containing toluol to

From the Department of Surgery of the George Washington University School of Medicine and the Surgical Department of the Gallinger Municipal Hospital, Washington, D C.
Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, New York, September 8-12, 1947.

prevent fermentation and were not pooled, but analyzed immediately after collection. Fractional urines studied were kept in individual containers, chemically studied separately and the total 24 hour results were computed by the addition of the individual figures.

2 Co-operative preoperative or convalescent surgical patients were used for the tolerance studies. They had no recognizable metabolic diseases and were not afflicted with ravages of serious surgical procedures or medical diseases (nephritis, hepatic diseases, nutritional deficiencies, etc.)

3 All blood samples were drawn from the opposite arm used for intravenous infusions into test tubes containing the anticoagulant heparin. These were not stored for longer than 12 hours at 4 degrees to 6 degrees centigrade before chemical analysis.

4 The total nitrogen and nonprotein nitrogen of the urine were obtained by Kjeldahl digestion, distillation and titration with .015 normal hydrochloric acid (13). Urea estimations were performed by digestion and nesslerization of the filtrate (13). All 24 hour urines were analyzed for total creatinine as a check against faulty collection of specimens. The creatinine output is rather constant under normal circumstances at a level of 0.9 to 1.3 grams per 100 cubic centimeters (13). Amino acid levels of blood and urine were estimated in milligrams by the Folin colorimetric method (2).

5 Control studies with phenolsulfonphthalein were conducted on all patients on whom the rate of excretion of this drug was used as an estimate of protein hydrolyzate absorption when given either by subcutaneous or intramuscular route. The control or normal test was executed thusly: Each patient drank 1000 cubic centimeters of water rather than the conventional 500 cubic centimeters so as to keep the fluid intake equal to the amount to be injected. After the fluid intake 1 cubic centimeter containing 0.6 gram of phenolsulfonphthalein was injected intramuscularly. Urine specimens were obtained at 1 hour and 10 minutes, 2 hours and 10 minutes and 3 hours and 10 minutes after the intramuscular injection and the percentage of dye excreted was calculated by colorimetric comparison with known standards (3).

6 The absorption test with protein hydrolyzate to which 0.6 gram of phenolsulfonphthalein is added was performed in the following manner: The day after the control study the same patients were infused either subcutaneously in 3½ hours or intramuscularly in 30 minutes with 1000 cubic centimeters of protein hydrolyzate containing 0.6 gram of phenolsulfonphthalein. Urine specimens were collected at designated intervals, the percentage of dye excreted was obtained by colorimetric comparison and these figures were then compared with the corresponding control values of excretion. The percentage excretion of normal for this particular patient implies the rate of removal of the dye with the protein hydrolyzate from the tissues and its appearance in the urine thus giving an approximate estimate of the rate of absorption from tissues of the solution containing the phenolsulfonphthalein.

7 Biopsy of muscle (vastus lateralis) is described to reveal the reaction of this tissue to repeated infusions of protein hydrolyzate solution.

INTRAVENOUS ADMINISTRATION

An overall reaction incidence of 0.7% per cent was found in two thousand and three (2003) intravenous infusions of 1000 cubic centimeters each in 320 preoperative and postoperative surgical patients.

The types of cases in which the solution was administered frequently represented the more ill surgical patients for it is this group which requires parenteral protein feeding. Some of the surgical diseases included in the group studied are listed for review: ruptured appendicitis with diffuse peritonitis, subtotal gastrectomy and anastomosis for duodenal ulcer or gastric carcinoma, chronic cholecystitis and cholecystectomy, multiple perforations of the intestine after gunshot or stab wounds of the abdomen, perforated peptic ulcers with closure, intestinal fistulas, carcinoma of rectum with combined abdominoperineal resection, essential hypertension and thoracolumbar sympathectomy and splanchicectomy and others.

The average amount injected intravenously by gravity at each infusion was 1000 cubic

centimeters, and the usual time required for this quantity was 1 or 1½ hours, thus a rate of 14 to 17 cubic centimeters per minute. Three thousand cubic centimeters per day were administered by continuous drip into the saphenous vein for 7 days to a patient with a small bowel fistula. Hence the largest single injection in the study is 21,000 cubic centimeters. There was no ascending thrombosis or phlebitis in this case. The largest quantity given to a single patient was 42,000 cubic centimeters in 14 days. Many other patients received large amounts for adequate protein therapy, for nitrogen balance in patients on parenteral feeding alone requires full and adequate dosage.

Fifteen reactions were found in the entire study. Three of these or 0.14 per cent were characterized by flushing, warmth, nausea, and forcible vomiting, and were labelled 'systemic reactions'. Ten, or 0.49 per cent, were typical 'pyrogenic reactions' which manifested themselves as chills, pyrexia, and tachycardia. Two 'allergic reactions' were noted in the same patient, thus an incidence for this type of 0.16 per cent. Of particular interest are the systemic reactions. The first two of these were the first reactions experienced in the entire study and occurred with the first batch of material investigated clinically. The third systemic reaction was noted 6 years after the above mentioned and was in a patient who had had a colon resection. He was receiving 3000 cubic centimeters of protein hydrolysate daily as part of a nitrogen balance study. The reaction occurred on the third day of the study with an infusion of hydrolysate which was being injected at an approximate rate of 15 cubic centimeters per minute. All of the manifestations were abated within 15 minutes after discontinuance of the infusion, but recurred after the infusion of 100 cubic centimeters at the original rate. No subsequent reaction developed when the remainder of the solution (500 c.c.) was infused at 8 cubic centimeters per minute. A sample of the solution causing the reaction was found to be sterile and contained only 50 per cent alpha amino nitrogen. The same patient received 13,000 cubic centimeters of the protein hydrolysate from the same batch causing

the reaction and no untoward manifestations were recorded.

In lieu of the recent observations of Hoffman Kozoll, and Osgood, of Smyth Lasichak and Levey, and of our recent observations (11) with rapid intravenous infusions of protein hydrolysate a blood amino acid level determination at the time of vomiting in the aforementioned reaction may have yielded significant data.

Both allergic reactions developed in the same case. The symptoms were puffed eyelids, large superficial wheals and shortness of breath after the receiving of 200 cubic centimeters at 15 cubic centimeters per minute on subsequent days. Past history of the patient elicited allergies to milk as a child, diarrhea or hives when she consumes chocolate and the same type of allergic reaction to amigen 5 months previously after 4 days of infusions of this latter preparation. Skin tests in this patient with protein hydrolysate solution produced a large allergic wheal. If patients can become sensitized to enzymatic hydrolysates of casein or blood it might prove a point of prevention to question all patients who are to receive intravenous infusions of hydrolysates as to whether they have had any previous infusion of protein digests and as to the development of any allergic reactions. Further skin testing before infusions on patients who have received hydrolysates would perhaps screen out sensitive individuals.

Since all of the intravenous infusions of protein hydrolysate reported in this entire study were given by the author or a technician we both had an excellent opportunity to observe the local manifestations. No acute ascending thrombophlebitis or ascending thrombosis was found in any case receiving 1000 cubic centimeters of hydrolysate solution in 1 or 1½ hours even though repeated infusions were given in either antecubital vein on subsequent days. Local thromboses were found in the veins at the site of repeated injections and infusions. It is the impression of this observer that thrombosis is no more frequent with hydrolysate solution than with similar infusions of 5 per cent dextrose solutions. Much of the local vein reaction can be diminished if the following procedures are

TABLE I.—AVERAGE BLOOD AMINO ACID LEVELS, DIFFERENCES, AND PERCENTAGE OF NORMAL CHANGE FOR TEN CASES RECEIVING 1000 C.C. OF PROTEIN HYDROLYSATE INTRAVENOUSLY IN ONE HOUR

	Amino acid	Difference	Normal change— above normal Per cent	Differences in per cent of normal change
Normal level mgm./100 C.	6.2			
3000 cc.— $\frac{1}{2}$ hour	7.9	+1.7	7	+11.7
3000 cc.—1 hour	9	+2.8	43	+46.2
After $\frac{1}{2}$ hour	8.6	+2.4	34.2	-7.7
After 1 hour	7.64	+1.44	23.2	-23
After $\frac{1}{2}$ hours	7.06	+0.86	13.2	-9
After 1 hour	6.17	+0	8	-4.6

conducted (1) select a smaller needle than the caliber of the vein to be used for infusions (2) execute the venipuncture by a sharp clean puncture through the anterior wall of the vein without damage to the opposite or posterior wall (3) insert the needle well into the lumen of the vein (4) avoid undue movement of the needle in the vein during infusion by adequate fixation of the needle, adaptor tubing and the extremity used and (5) avoid long continued infusions in the same vein with a single venipuncture. The hazards of prolonged intravenous infusions are related in the following experience. A patient had received four individual infusions of 1000 cubic centimeters each of protein hydrolysate in the right arm at an approximate rate of $1\frac{1}{2}$ hours. Another 1000 cubic centimeters of hydrolysate was inadvertently given slowly over a 5 hour period in the left arm. That night the patient noticed severe pain and soreness in the upper left arm and at the site of the injection in the antecubital fossa. Examination the next morning revealed complete thrombosis of the medial superficial vein of the upper arm extending from the antecubital fossa to the axilla. The skin adjacent to the vein showed inflammation the entire vein was exquisitely tender to palpation and movement of the arm produced discomfort to the patient. Four days of compressing were required to alleviate the manifestations. Hence because the discomfort was too great, it was not feasible to use the left arm for further infusions during the patient's hospital stay. The life of available accessible veins in the arm of patients on

intravenous feeding may be prolonged by the plan of starting well down on the forearm for the first infusions and then gradually ascending to the antecubital fossa with the repeated injections.

Few patients who have received 3000 or 4000 cubic centimeters of protein hydrolysate daily as part of an investigation of nitrogen balance have caused us any difficulty with successful venipuncture after numerous intravenous infusions. In a study of parenteral hydrolysates in parenteral nutrition Koop and associates report thrombosis as a common occurrence with all preparations used for considerable periods. "The tendency to thrombosis was subject to marked variation between individual patients and in several patients the infusion of hydrolyzed protein had to be stopped for this reason. Venous thrombosis appeared to be the chief limiting factor in parenteral nutrition (7).

Blood amino acid levels and urine chemical changes with intravenous injection of 1000 cc. protein hydrolysate in one hour. Ten preoperative or postoperative surgical patients who did not manifest any gross evidence of nutritional deficiency or serious surgical maladies were used for this study. The average serum protein was 6.8 grams per 100 cubic centimeter of serum for the 10 subjects before the infusions. The intravenous injection of 1000 cubic centimeters of hydrolysate was performed in the right arm in the antecubital fossa by gravity in 60 minutes thus an approximate rate of 17 cubic centimeters per minute. The blood samples were drawn from

Chart 1. Intravenous protein hydrolysate.

the left or opposite arm before the infusion, after the infusion of 500 cubic centimeters, after the infusion of 1000 cubic centimeters, 30 minutes, 1 hour $1\frac{1}{2}$ and 2 hours after completion of the intravenous injection. The urine samples were collected, when possible, at intervals corresponding to the drawing of blood and throughout the 24 hour period. Thus a total 24 hour urine was obtained fractionally.

The average blood amino acid levels, the differences, and percentage of normal change for the ten cases are shown in Table I.

The amino acid nitrogen rose 21.7 per cent above normal or 1.4 milligrams per 100 cubic centimeters of serum after the infusion of 500 cubic centimeters of protein hydrolysate. The maximum individual rise for this period was to 8.9 milligrams or a 2.9 milligram rise above the normal level for this period. The least rise was 0.9 milligram. The average blood amino acid rise after the injection of the latter 500 cubic centimeters was 1.3 milligrams or 20.5 per cent above the preceding level. Hence the average total rise with the injection of 1000 cubic centimeters of protein hydrolysate is

42.2 per cent above normal or a 2.6 milligram rise from the base reading. These figures indicate a higher percentage rise for the first 500 cubic centimeters as compared to the second. The difference may be explained by the fact that blood amino acids are being removed throughout the period of injection and that the rate of metabolism may somewhat parallel the level of amino acids in the blood. During the first half hour after the end of the 1000 cubic centimeter infusion 7.7 per cent decrease in amino acids is noted and a 13 per cent removal occurs in the following 30 minutes. Therefore 20.7 per cent of the circulating amino acids are utilized in the first postinfusion hour. The following 1 hour period showed a 13.5 per cent decrease in amino acid level. Survey of the individual cases reveals a close correspondence to the average figures presented. Finally 2 hours is the usual time required for the removal of the major part (81 per cent) of maximum total circulating amino acids resulting from the injection of 1000 cubic centimeters of protein hydrolysate in 1 hour.

Amino acids were not detected in any of the urine samples analyzed. The total urinary nitrogen determinations revealed 24 hour outputs ranging between 9.6 grams and 12.3 grams of nitrogen with an average output of 10.56 grams of nitrogen per day. This figure is well within the range of the average output of convalescing ambulatory surgical patients on a regular hospital diet in our institution. The total creatinine values varied between 1.1 and 1.4 grams and averaged 1.16 grams per 24 hour urine sample—a figure that represents the usual total output for creatinine. This is used as a guide for the correct collection of all urine specimens during the 24 hour study period. The effect of the intravenous administration of 1000 cubic centimeters of protein hydrolysate in 1 hour on the blood amino acid nitrogen and the urinary excretion of nitrogen and amino acids is shown in Chart 1.

No nausea or vomiting was seen in any of the 10 cases with the infusion of 1000 cubic centimeters of protein hydrolysate in 1 hour or at a rate of 16 cubic centimeters to 17 cubic centimeters per minute. Recent observations to be reported show that vomiting occurs

with protein hydrolysate when it is given at a rapid rate varying between 50 cubic centimeters per minute and 140 cubic centimeters per minute. The blood amino acid levels at this point are 14 milligrams per 100 cubic centimeters of serum or more (11).

SUBCUTANEOUS ADMINISTRATION

Four hundred and twenty subcutaneous infusions of 1000 cubic centimeters of protein hydrolysate have been infused into 136 patients without any local difficulties or failure of absorption. Twenty five or 50 cubic centimeters of 1 per cent novocain is added to the solution partially to novocainize the area of injection. Slow even infusions without undue distention permit the most comfortable and readily absorbed subcutaneous infusions. It is a mistake to overdilate subcutaneous tissues by rapid infusions of protein hydrolysate. The practice of rapidly infusing 1000 cubic centimeters or more, stopping the infusion until absorption has taken place and repeating this process four or five times until 1000 cubic centimeters is administered is faulty for it produces local discomfort, pain delays or prolongs absorption and increases the incidence of local complications.

In this study the site used for subcutaneous infusions was the anteromedial aspect of both thighs. A 2½ inch, No. 18 or 19 gauge needle is most commonly employed. When feasible, a novocain intradermal wheal is made before insertion of the needle into the subcutaneous tissue. The usual time required for the infusion of 1000 cubic centimeters of protein hydrolysate varies between 2½ and 4 hours. The time factor is influenced by the degree of hydration, the amount of subcutaneous fat, and the age of the patient. Elderly patients who are not too thin seem to absorb the fluid more readily than the average young or middle aged adult. A normal amount of subcutaneous fat aids absorption whereas excessive amounts of soft fat decrease absorption and enhance local complications. It is our common practice to refrain from using the subcutaneous route in patients with pendulous fat thighs. The patients receiving protein hydrolysate subcutaneously are those on parenteral feeding either before or after surgery. Another group

TABLE II.—BLOOD AMINO ACID LEVELS AFTER SUBCUTANEOUS INFUSION OF 500 C.C. OF PROTEIN HYDROLYSATE IN ONE AND ONE HALF HOURS

Case	1	2	3	4	5	6	7	8	9	10	Average values	Per cent of normal
Normal level 100 c.c./mgm.	6.1	6.3	6.8	6.4	6.6	5.5	5.8	6	6.0	6	6.17	
After 50 c.c.	6.6	6.6	6.9	6.6	6.7	5.8	6	6.6	6	6.6	6.47	4.9
After 500 c.c.	7	6.9	7.2	7.2	6.9	6.3	6.3	6.8	6.6	7	6.91	3
After 1/2 hour	7.4	7.0	7.3	7.3	7.3	6.6	6.3	7.3	6.7	7.4	7.06	15.5
After 1 hour	7.4	6.9	7.3	7	7.3	6.3	6.4	7.0	6.6	7.3	6.97	3
After 1 1/2 hours	7.0	6.8	7	6.6	7	6	6	6.8	6.3	7	6.7	1
After 2 hours	6.8	6.4	6.9	6.3	6.9	5.9	6	6.4	6	6.6	6.46	5.6

of patients who frequently are given this solution subcutaneously are infants or children but these are not included in this report. We usually give only 1000 cubic centimeters a day to adults by the subcutaneous route. However, on occasions it becomes necessary to administer larger amounts to those patients who have a limited number of accessible veins or to those with cardiac diseases in whom the possibility of cardiac overloading is imminent. The largest single amount administered subcutaneously was 23 000 cubic centimeters over a 14 day period. In one instance a patient was kept in positive nitrogen balance for 8 days with parenteral protein hydrolysate subcutaneously as the sole source of proteins. She received 2000 or 3000 cubic centimeters daily by this route without any severe local reactions. After the fourth day the thighs were tender and painful but we continued the therapy by the same route for 4 subsequent days.

Blood amino acid levels and urine chemical changes with subcutaneous injection of 500 c.c. of protein hydrolysate in one and one half hours. Ten uncomplicated postoperative inguinal hernia patients were selected for these tolerance studies. These patients had been operated upon either 6 or 7 days previously were on regular hospital diets, and ambulating. The 500 cubic centimeter infusion was administered into each thigh on the anteromedial aspect by gravity at a rate of 5 to 6 cubic centimeters per minute. At this speed there was no overdistention of the tissues or excessive bulging in the injected area. One per cent novocain was not used in these cases. Blood samples were drawn from either arm before

the injection after the infusion of 250 cubic centimeters after 500 cubic centimeters and 30 minutes 1 hour $1\frac{1}{2}$ and 2 hours following the completion of the infusion. A total 24 hour urine was collected fractionally the day of the infusion. Table II describes the changes in the blood amino acids.

The average amino acid level in these 10 patients was 6.17 milligrams per 100 cubic centimeters of serum and the individual findings varied between 5.5 milligrams and 6.8 milligrams per 100 cubic centimeters. After the infusion of 250 cubic centimeters a 4.9 per cent elevation was noted, or an average rise of 0.3 milligram per 100 cubic centimeters of serum. The injection of the next 250 cubic centimeters produces an 8.1 per cent rise from the previous figure or a 13 per cent increase above the original base level. There is a continued rise of the amino acids by 0.1 milligram in the 30 minute period following the completion of the injection. During the oncoming 30 minute period a slow decrease occurs in the blood amino acids. The findings in sequence are 0.1 milligram 1.5 per cent of normal 0.2 milligram 3.0 per cent of normal and 0.3 milligram 4.9 per cent of normal—a total decrease at this point (2 hours after completion of the infusion) of 0.6 milligram which represents 9.4 per cent of the normal level. However the readings at this time still elicit a 5.1 per cent elevation of normal. From the previous rate of removal we may infer a decrease to normal within another hour. Comparison of the rapid decrease in blood amino acids after intravenous infusion and the gradual slow decrease found with subcutaneous projects the idea of a gradual absorption of protein solu-

TABLE V—AVERAGE LEG MEASUREMENTS AND EXCRETION OF PHENOLSULFONPHTHALEIN AFTER SUBCUTANEOUS INJECTION OF 1000 C.C. OF PROTEIN HYDROLYSATE IN TWO AND ONE HALF HOURS IN FIVE CASES

Time	7½ min.	8½ min.	After 1 hour	After 2 hours	After 3 hours	After 4 hours	Total excretion

Control c.c. PSP per cent excretion			49	5	5.6		79.6
1000 c.c. P.H. and 1 c.c. PSP subcutaneously per cent excretion of PSP	8	1	19	6	9	9	73
Per cent excretion of control	9.4	23.9	46.8	68.3	81	89.7	89.7
Leg measurements							
Right	+0.75"	+1.5	+1.23	+0.55"	+0.19		
Left	+0.75"	+1.5"	+1.0"	+0.5"			

The following day the absorption test, with 1000 cubic centimeters of protein hydrolysate subcutaneously to which is added 0.6 gram of phenolsulfonphthalein, is conducted on the same patient. The details of the test are: The patient voids and the urine specimen is discarded. 1000 cubic centimeters of protein solution containing the dye is injected into the subcutaneous tissues in an average time of 158 minutes or about 2½ hours at an infusion rate of approximately 6.25 cubic centimeters per minute; urine specimens were collected after the injection of 500 cubic centimeters after 1000 cubic centimeters, and 1, 2, 3 and 4 hours following the completion of the infusion. The percentage of dye excreted for each period was calculated by colorimetric comparison. Leg measurements were obtained on each thigh during and after the infusion at regular intervals until the visual distention had disappeared; lastly, the percentage excretion of dye found with each period after the subcutaneous infusion of the hydrolysate and dye was calculated in terms of percentage of the total amount excreted by the control test performed the day before. Phenolsulfonphthalein dye has been used as an indicator for absorption (1). The results are depicted in Table V.

An average of 49 per cent of the dye was recovered in the urine 1 hour and 10 minutes after the injection of 1 cubic centimeter of phenolsulfonphthalein. The individual findings varied between 40 and 60 per cent. This represents the largest amount of dye excreted

during the 3 hour period following the injection. The 5 cases revealed an average total excretion of 79.6 per cent and 85 per cent was the greatest amount per case.

The urinary excretion of phenolsulfonphthalein when injected slowly with 1000 cubic centimeters of protein hydrolysate is distinctly different from that seen in the control. One hour after completing the injection a 39 per cent dye excretion is seen whereas 49 per cent was recovered in the control test at this point. The average figures of excretion for the period during and 1 hour after the injection are 8 per cent after 500 cubic centimeters is infused, 12 per cent following the next 500 cubic centimeters infusion and 19 per cent in the first post infusion hour. Two hours after completing the infusion, 16 per cent of the dye is recovered, 9 per cent in the 3 hour period and 9 per cent in the last or 4 hour interval. Hence a total excretion of 73 per cent of dye injected is noted in a 6½ hour period—6.6 per cent less than the amount recovered in a 3 hour period after injection of 1 cubic centimeter of dye subcutaneously.

The excretion figures obtained with the injection of dye dissolved in 1000 cubic centimeters of protein hydrolysate infer a rather steady and even absorption but with a maximum period at the end of 500 cubic centimeters and 1 hour after the injection of 1000 cubic centimeters. An 89 per cent excretion of the control is found in the 6½ hour period. Further, 72 per cent of the total excretion during the 6½ hour period occurs in the 4 hour period following the infusion.

The leg measurements closely correlate the blood amino acid levels previously described and the aforementioned excretion studies for the subcutaneous infusion of protein hydrolysate. The maximum increase in girth is noted at the end of the infusion (+1.5 inches in each leg). The enlargement subsides to normal within 3 hours after the injection.

A maximum blood amino acid level at the end of the subcutaneous administration and for 1 hour thereafter and the maximum excretion of dye at the same periods, indicate maximum absorption during this period. The gradual decline in the blood amino acids, the excretion of dye and the leg size during the next 3 to 4 hours verify previous impressions of a slow rather steady absorption for fluid given subcutaneously. Since the absorption time of subcutaneous infusion is time consuming in adults it is likely that subcutaneous infusions should not be given more frequently than every 8 to 12 hours.

INTRAMUSCULAR ADMINISTRATION

The intramuscular route has been used chiefly for the injection of small amounts (1 c.c. to 10 c.c.) of solutions and drugs in adults. Muscle tissues are vascular and contain a large supply of lymphatics hence absorption should be rapid and adequate. One of the early reports on the use of intramuscular route was that of Nasseau in 1926 who described encouraging results. Later descriptions appeared in Germany (Stamm). Glaser recommended the lateral and anterolateral surfaces of the thigh.

Our interest in intramuscular infusions of large quantities of protein hydrolysate stemmed from the experience of the author with plasma intramuscularly and the discomfort associated with lengthy subcutaneous infusion. Patients on parenteral therapy alone require 3000 to 4000 or more cubic centimeters per day. In view of the hospital management of surgical patients the usual method of administering 3000 cubic centimeters of fluid per day is to give 1000 cubic centimeters intravenously in the morning, 1000 cubic centimeters subcutaneously in the afternoon and 1000 cubic centimeters intravenously in the evening. By this plan the patient is immobilized for at

least 6 to 8 hours of the waking period, if all of the infusions are administered with ease (1½ hours for intravenous and 2½ to 4 hours for subcutaneous). Thus the patient is able to move about for only 5 hours of his hospital day. If the infusions require longer periods, such as 3 to 4 hours for intravenous, one can readily see that the patient is on his back all day if he is to receive adequate fluid and nutrition.

Technique. One thousand cubic centimeters of protein hydrolysate can be infused into the vastus lateralis of each leg simultaneously within 30 minutes without undue discomfort. The site selected for the infusion is the lateral at a point midway between the anterior and posterior surfaces and at the junction of the upper and middle thirds. A 2½ inch No. 15 to 18 gauge needle is used with the bottle suspended 3 feet from the level of the thigh, a Y connection is used so that both thighs are injected at the same time. One per cent or 2 per cent novocain to the amount of 50 cubic centimeters is usually added to each bottle for local novocainization. It is best to have the legs flexed at the knee so as partially to relax the iliotibial band. The needle is thrust sharply at a 45 degree angle to the long axis of the thigh with the point directed upward or cephalad. After the fascia lata is pierced the needle is inserted into the substance of the muscle at a 15 degree angle to the side of the thigh. There is a sense of give when the needle pierces the fascia. It is important to keep the end of the needle away from the bone; the needle should not be submerged beyond the middle of the transverse diameter of the vastus lateralis at the point of injection. No taping of the needles to the skin is necessary as the fascia lata will tend to fix the needle. The stopcock in the set is opened wide and the fluid is allowed to pour in. The first 200 to 300 cubic centimeters are administered in a matter of 3 to 4 minutes. Not infrequently the patient complains of a sense of fullness in the legs and describes a smarting sensation which disappears after the infusion of about 300 cubic centimeters. The flow is then slightly decreased but still continues at a very rapid rate. As the last 200 to 300 cubic centimeters are approached, the flow decreases still more but

TABLE VI.—BLOOD AMINO ACID LEVELS AND UREA NITROGEN AFTER RAPID INTRAMUSCULAR INJECTION OF 1000 C.C. PROTEIN HYDROLYSATE IN THIRTY MINUTES IN BOTH THIGHS

Case	1	2	3	4	5	6	7	8	9	10	Average amino acid	Average blood urea
Normal level 100 c.c./mgm.	6	6.4	5.8	6	6.3	6	5.9	6.5	6.4	6.6	6	1.4
After 1000 c.c. P.H. intramus. in 30 min	7.4	7.3	6.9	7.8	7.8	7.0	6.8	7.8	7	7.5	7.16	8
After 1 hour	7.6	7.5	7	7	7.6	7.3	7.5	7.8	7.5	7.7	7.4	6
After 2 hours	7.4	7.5	6.8	6.7	7	7	7.0	7	7	7.5	7	1.8
After 3 hours	6.4	6.7	5.9	6.3	7	6.4	6.5	6.7	6.6	6.6	6.5	8
After 24 hours	6.1	6.5	5.7	5.9	6.4	6	6	6.4	6.5	6.5	6.5	3

is not slow enough to count the drops accurately in the "vaco drip". There is a bulging in the lateral compartment of the thigh. There is no pain after the early part of the infusion but patients complain of a heaviness in the leg following the injection and this is frequently described as a "dead leg". This sensation disappears with absorption. Few patients have any difficulty with ambulation after the total infusion. In the early part of our experience with intramuscular infusions we gave 1000 cubic centimeters into each limb but this produced excessive distention and tension. This distention was occasionally severe enough to produce the leakage of fluid from the puncture site. Needles in which holes were bored in the sides were also tried. These needles permitted a faster flow than is seen with the standard needles.

One hundred and seventy intramuscular infusions of 1000 cubic centimeters of protein hydrolysate have been administered to 78 patients without recognizable local reactions, irritations or failure of absorption.

Blood amino acid levels, urea nitrogen and urine chemical changes after rapid intramuscular injection of 1000 c.c. protein hydrolysate in thirty minutes. This study was performed with 10 uncomplicated postoperative surgical patients. The liter of hydrolysate was administered in 30 minutes by the previously described technique. Blood samples were drawn before the infusion and after the 1000 cubic centimeter injection 1 hour, 2 hours, 3 hours, and at the end of the 24 hour period following the administration. Fractional samples of urine were collected throughout the 24 hour period.

The individual amino acid levels, the average amino acid levels and the average blood urea nitrogen for the 10 individuals studied are presented in Table VI. As will be noted the maximum rise occurs at the end of the infusion and in the first hour following the end of the injection. A 15.4 per cent or +1.0 milligram per 100 cubic centimeters of serum rise is seen with the end of the injection. A maximum response of 1.4 milligrams developed in 1 case and the least effect was represented by a 0.9 milligram elevation for this period. One hour following the injection the average rise was 0.2 milligram above the previous level with total rise above normal of 19.3 per cent. Further analyses of the blood levels found at 1 hour after end of the infusion indicate no rise in 3 instances. During the next 2 hour period a decrease of 17.8 per cent is seen—in order the figures are 13 per cent and 4.8 per cent decreases. The amino acid blood levels are normal at the end of the 24 hour period. These figures indicate maximum absorption with the completion of the infusion and an almost equal absorption rate within the first hour following the injection. The rather precipitous decline in the second postinfusion hour shows that the greater percentage of the injected protein hydrolysate is absorbed within a 2 or 2½ hour period following the injection.

The average blood urea levels performed at the same intervals as the blood amino acids are not significant. Further the total nitrogen output for the 24 hours of study varied between 11.1 and 13.1 grams, and averaged 12.4 grams.

A composite presentation of the above findings is illustrated in Table VII.

TABLE VII.—AVERAGE BLOOD AMINO ACID LEVELS, DIFFERENCES PERCENTAGE OF NORMAL CHANGE AND AVERAGE BLOOD UREA NITROGEN FOR TEN CASES AFTER RAPID INTRAMUSCULAR INJECTION OF 1000 C.C. PROTEIN HYDROLYSATE IN THIRTY MINUTES IN BOTH THIGHS

	Amino acid	Difference	Per cent of normal change—above normal	Differences in per cent of normal change	Urea nitrogen
Normal level 00 c.c./mgm.	6				4
After 1000 c. P.H. intramuscularly	7.6	+1	5.4	+13.4	12.8
After 1 hour	7.4	+	19.3	+3.9	6
After 3 hours	7	+0.8	13	-6.8	12.8
After 3 hours	6.5	+0.3	4.8	-8	8
After 24 hours	4				2

Average blood amino acid levels, leg measurements and rate of absorption as determined with phenolsulfonphthalein excretion as an indicator after the rapid intramuscular injection of 1000 c.c. of protein hydrolysate in about thirty minutes in 5 cases. The method of injection is as described. The procedure for investigation is similar to that related under subcutaneous infusions except for the following details: (1) control injection of dye (1 c.c.) was made into the vastus lateralis of the leg; (2) blood samples were drawn at the same intervals as the collection of urine samples.

The injection rate in this experimental study and in the other infusions performed for clinical indications is about 36 cubic centimeters per minute.

Table VIII demonstrates the findings.

The amount of dye excreted in the control test closely resembles the findings previously described in the subcutaneous group viz. 79.6 per cent in 3 hours in subcutaneous and

69.4 per cent in 3 hours in the intramuscular series.

After the intramuscular injection of the hydrolysate solution with 0.6 gram of phenol sulfonphthalein 32 per cent of dye is excreted 1 hour after the total infusion, 22 per cent at the end of the next hour, 11 per cent following the third hour and 2.2 per cent after 4 hours. In percentage excretion of normal the above figures represent in the same sequence, a 46 per cent, 77 per cent, 93 per cent, and 96 per cent excretion of normal.

Five hundred cubic centimeters of fluid or approximately 250 cubic centimeters in each leg causes an increase in size of 1.3 inches and with the total injection the thighs are increased to about 2.6 to 2.75 inches above normal. The thighs begin to decrease soon after the end of the infusion by about 1 inch an hour so that they have returned to normal size within 3 hours after the completion of the liquid infusion. Therefore, 1000 cubic centimeters of

fluid injected rapidly into the vastus lateralis is absorbed within a 2 or 2½ hour period. Hence one can administer intramuscular infusions of similar quantity every 4 to 6 hours.

A male patient with peritonitis from a perforated duodenal ulcer was given daily injections of 1000 cubic centimeters of protein hydrolysate solution in each thigh rapidly (30 minutes) for 7 successive days as part of his fluid therapy. A biopsy of the vastus lateralis was taken the day following the last injection. Gross examination of the muscle did not reveal any changes in color, striations or configurations. Microscopic sections showed normal muscle bundles. There was no separation of the muscle fibers, fibrosis, fragmentation, or cellular infiltration as evidence of inflammation or irritation.

ADVANTAGES AND DISADVANTAGES OF EACH ROUTE

In view of this report, it seems evident, that parenteral protein hydrolysate prepared by enzymatic digestion of bovine blood is a safe solution in surgical patients when given intravenously, subcutaneously, and rapidly intramuscularly. These findings verify an earlier report (12).

Intravenous administration of fluids is by far the most commonly used route. Though it has the advantages of direct introduction of medication and ease of administration of large amounts at one time or continuously, it has numerous disadvantages. An intravenous infusion is only as effective as the flow through the needle, and the flow through the needle is directly related to the correct introduction of the needle into the vein. The ease or difficulty encountered with venipuncture is dependent on (1) accessibility of the veins (collapsed or masked by subcutaneous fat) (2) size of the veins (3) thickness of the wall of the veins (4) degree of fixation of the vein (5) size of the needle in relation to the size of the vein, (6) sharpness of the needle, (7) the degree of bevel of the needle (8) cleanliness of the needle (9) experience of the individual doing the injection (10) position of the needle in the vein (complete incomplete angulation etc.) (11) age of the patient (12) co-operation of the patient' (White, 13)

Though intravenous medications have been refined to reduce reaction incidences, the danger of reactions is still an imminent one. Most reactions depend on factors within the patient, those in the equipment, and those due to the solution. The reactions which may result from faulty equipment are due to pyrogens, contaminants rubber tubing, or alkalies. Too rapid infusions of solutions may cause overloading, pulmonary edema, or systemic reactions such as vomiting, flushing etc. These studies indicate that the tolerance of protein hydrolysate is great. As much as 25 to 30 cubic centimeters may be injected per minute in 1000 cubic centimeter doses without fear of frequent systemic reactions. Vomiting and nausea are seen only if 50 to 150 cubic centimeters per minute is injected in quantities of 700 to 1800 cubic centimeters. A recent report by Smyth and associates indicates that the incidence of nausea with hydrolysates depends on the amino acid composition rather than on the average rate of administration or on the plasma amino acid nitrogen level. This author also indicates that there may be a close relationship between glutamic and aspartic acid contents with nausea and vomiting after intravenous injection. The solution studied and presented herein contains 10.34 per cent glutamic acid and 4.26 per cent aspartic acid.

After the injection of 50 grams of protein hydrolysate intravenously at 17 cubic centimeters per minute there is an average rise of 2.6 milligrams of amino acids per 100 cubic centimeters of serum or a 42.2 per cent elevation above normal. Two hours later the major part of the circulating amino acids is removed. A point of interest is the slight decrease during the first postinfusion hour and the maximum removal in the next hour. Hoffman Kozoll and Osgood report the following findings with "parenamine." Injection of 45 grams of parenamine intravenously at slow speeds produced an average plasma amino acid rise of +4.9 milligrams per 100 cubic centimeters during the injection with a return to normal in 2 hours. The difference in our amino acid levels and those reported by Hoffman and associates may be partially due to the difference in amino acid content of the two preparations. The preparation of protein

preoperative and postoperative surgical patients there were 0.72 per cent reactions 0.14 per cent were systemic, 0.49 per cent were pyrogenic, and 0.09 per cent were allergic. The systemic reactions were seen only with the first batch of material investigated in the early part of the investigation. The average rate of infusion varied between 12 and 17 cubic centimeters per minute, a speed commensurate with practical administration of fluids.

4. No acute ascending thrombophlebitis or ascending thrombosis was found in any case receiving 1000 cubic centimeter infusions in 1 or 1½ hours even though repeated infusions were given on subsequent days in either antecubital veins. A procedure for decreasing the local thrombosis and the disadvantages of prolonged infusions are presented.

5. The blood amino acids rise 2.6 milligrams per 100 cubic centimeters or 42.2 per cent above normal after the infusion of 1000 cubic centimeters of protein hydrolysate in 1 hour. Two hours is required for the removal of excess amino acids accumulating in the blood after the injection. No increase in urinary nitrogen or amino acids is found in the urine with the intravenous administration of 1 liter of hydrolysate solution.

6. Four hundred and twenty subcutaneous infusions of 1000 cubic centimeters were given at a rate of 6.25 cubic centimeters per minute in 126 patients without failure of absorption or local difficulties.

7. Subcutaneous infusions of 500 cubic centimeters of protein hydrolysate in both thighs and in 1½ hours cause a 13 per cent rise in blood amino acids with an average maximum rise to 6.91 grams per 1000 cubic centimeters. This rise continues in the next 30 minutes but then decreases and has returned to normal 2 hours after the end of the injection. Absorption studies as indicated by the excretion of absorbed phenolsulfonphthalein indicate that 6½ hours are required for the introduction and absorption of 1000 cubic centimeters of protein hydrolysate. Hence only 1000 cubic centimeters of fluid can be given every 8 to 12 hours by the subcutaneous route.

8. A method of estimating absorption of fluids from subcutaneous and intramuscular

tissues with the excretion of absorbed phenol sulfonphthalein is presented.

9. One hundred and seventy intramuscular injections of 1000 cubic centimeters of protein hydrolysate in 78 patients at a rate of 33 cubic centimeters per minute show rapid absorption in 3 hours, no irritations or local reactions, no failure of absorption and a negligible amount of pain or discomfort.

10. Blood amino acid levels, after the intramuscular injection of 1000 cubic centimeters in 30 minutes indicate a maximal rise at the end of the infusion and a decrease to near normal within 3 hours after the injection. Absorption studies reveal similar findings in which 93 per cent is absorbed in 3 hours after the rapid infusion of 1000 cubic centimeters into the vastus lateralis.

11. Pathologic slides do not show any abnormal tissue reaction in a patient who received into the same leg 1000 cubic centimeters on 7 consecutive days.

12. A comparison of intravenous, subcutaneous intramuscular infusions is made and the advantages and disadvantages of each route are discussed.

13. Bovine protein hydrolysate is a safe parenteral fluid for patients who require proteins by intravenous, subcutaneous and intramuscular routes.

CONGENITAL OBSTRUCTION OF THE BILE DUCTS

IN recent years, a greater interest in surgical conditions of infancy and childhood has resulted in the increasing number of congenital anomalies that are reported. With increasing experience successful results are being obtained in the surgical treatment of these conditions, many of which, 30 years ago were uniformly fatal. Developmental anomalies causing obstruction in the extrahepatic bile ducts are examples of these conditions. Jaundice in the newborn is a very common finding and the case of jaundice that is the result of a congenital obstructive lesion in the extrahepatic ducts must be recognized in treating icterus in early life. This diagnosis may be difficult to establish in the first two to three weeks of life. Fortunately as far as prognosis goes it is not essential that diagnosis be established this early. The prognosis seems equally favorable in those cases that are amenable to surgical treatment even though the diagnosis is not established for several

weeks. It is desirable however that these infants be operated on before the fourth or fifth week of life. While the treatment in these cases is surgical, there is always ample time to be sure of the diagnosis.

The diagnosis is made largely by the exclusion of other causes of jaundice in early life. The differential points are usually easily determined. The following causes must be considered and excluded. Icterus neonatorum, or physiologic jaundice is generally not serious and usually disappears between the second and third week of life. While the degree of icterus present in physiologic jaundice may at first be the same as that in obstructive jaundice it does not progress. There is seldom an enlarged liver and the jaundice soon starts to subside. The stools contain bile and there is seldom bile in any large amount in the urine.

Icterus due to erythroblastosis fetalis comes on early and examination of the blood smear may show an increased number of erythrocytes. The spleen is enlarged rather early in this disease which is not the case in congenital obstruction of the bile ducts. Appropriate laboratory tests of the child's and the mother's blood will promptly confirm or exclude the presence of Rh incompatibility and any abnormal antibodies. In erythroblastosis fetalis, unless suitable treatment by appropriate transfusion is instituted there may be an early fatal outcome. However it is well to remember that in the recovery stage of erythroblastosis fetalis with jaundice there may be an obstructive phase due to severe liver damage. If the suitable laboratory tests of the child and mother as referred to above have not been done they should be performed at this stage to rule out this possibility as a cause of the icterus.

Icterus in the newborn caused by hemolysis whether from sepsis or from hemolytic crises, is not accompanied by the acholic stools characteristic of congenital obstruction of the bile ducts, nor is there a significant amount of bile in the urine. The icteric index is not increased and the symptoms are not, as a rule, progressive. In familial hemolytic icterus there is a striking increased fragility of the red blood cells which is the important laboratory finding.

Syphilis as a cause of jaundice, will be shown by appropriate examination of the patient's and parents' blood and usually the x-ray examination will give confirmatory evidence of syphilis in the patient's bones.

In congenital obstruction of the bile ducts, the jaundice is prompt in appearance, often being present at birth or very shortly thereafter. Characteristically it becomes slowly but progressively more intense as the days and weeks pass and it has a rather peculiar greenish yellow color rather than the bright yellow tinge seen in other types at this age. The stools are clay colored or white, show no bile from the start and continue to be acholic. Very occasionally, a positive test for bile may be obtained or the stool may show gross evidence of bile on the surface. Such findings have been observed in our series where operation has proved that there was atresia or even complete absence of the extrahepatic ducts. To explain this finding it is presumed that a certain amount of bile may be excreted into the gastrointestinal tract from the intestinal mucosa, the bile being carried there by the blood stream.

Cases of congenital atresia show no evidence of sepsis as a cause for the jaundice unless there be a concomitant infection. The icteric index is elevated. In our series these ranged from 50 to 325, the average being 150. The fragility of the red cells is normal or even de-

creased. The urine is dark colored and will persistently give a positive test for hile pigment.

In other words, the diagnosis is arrived at with considerable certainty by excluding other causes of jaundice. In doubtful cases nothing is lost by waiting a sufficient period of time to exclude these causes. The general condition of these patients remains surprisingly good even after two to three months. It is however desirable to operate as soon as the diagnosis is established which is usually possible by the fourth week. Unless the condition is very advanced abdominal findings are confined to an enlarged liver, the edge of which may extend well down below the costal margin. It is sometimes possible to feel the roughening characteristic of biliary cirrhosis. Ordinarily the spleen is only slightly enlarged, if at all. In advanced cases ascitic fluid may be present. The state of nutrition is usually surprisingly good, though the older infants may give some history of fat intolerance when on the ordinary formula for their age. Blood studies rarely show anything other than a secondary anemia. Surprisingly enough the clotting time is seldom increased, particularly in infants under two to three months of age. The prothrombin values may be somewhat lowered though this is not always the case. The infant shows nothing like the profound toxemia that is usually present when the icterus is due to sepsis. The gross findings associated with these obstructions are a generalized persistent and increasing icterus with a gradually increasing size of the liver.

The treatment is surgical. The extrahepatic biliary system should be very carefully inspected through an incision of adequate length, preferably a right rectus incision. The procedure takes time and must be done with great care and with particular attention to the control of hemorrhage. The gall bladder is sought for first and if present is followed down to the

area of the hepatic and common duct. If the gall bladder obviously contains bile, the prognosis for that individual becomes much more favorable. Oftentimes, the gall bladder is rudimentary and even when it has a lumen it may prove to contain only a clear viscid fluid with no bile pigment, which indicates that there is no communication between this organ and the other extrahepatic ducts. Distention of the gall bladder with saline solution may give valuable information as to whether it communicates with the hepatic and common ducts. If these ducts communicate but are very small such distention permits of their easier identification. The gall bladder may be absent. A great variety of anomalies may be encountered. The essential finding as far as the chance of successful surgery is concerned is the presence of the hepatic duct. If nothing in this region can be found, the prognosis is hopeless. Even a very small hepatic duct can be successfully anastomosed to the duodenum and this is usually best done over a small piece of soft rubber catheter which should be not more than two centimeters in length. A longer tube may not be passed with ease after healing has taken place. If the hepatic duct, a cystic duct, and a gall bladder are present and continuous the operation of choice is to anastomose the gall bladder to the duodenum. This procedure is far better than anastomosing it to the stomach. If there is any appreciable length to the common duct, however it is better to anastomose the common duct to the duodenum.

The usual careful attention to preoperative and postoperative care, particularly as regards fluid and electrolyte balance must be observed. In about one fifth of the cases, the structural anomaly present will permit of some successful anastomosis between the extrahepatic ducts and the gastrointestinal tract. In the remaining and discouragingly large percentage of

cases however no extrahepatic ducts are present. Many measures have been employed in such cases to create an artificial communication between the liver itself and the gastrointestinal tract. These efforts are usually futile, because postmortem examination of patients who have no extrahepatic ducts, does show in a large percentage of cases, an associated intrahepatic developmental pathology of such a degree that there is practically speaking no biliary tree of sufficient size or development to permit any form of anastomosis between the liver and the gastrointestinal tract that will effectively drain bile.

The infants who have been successfully operated on however have shown a very satisfactory development. They have not shown evidence of liver damage for as long as 15 years after operation. This is surprising when one considers the apparently advanced state of cirrhosis present at the time of operation. It has been particularly interesting that they have not shown any notable tendency for a retrograde cholangitis, even though the stoma between the bile duct and the intestine has, in most cases, been relatively large and presumably with a complete absence of any sphincter action. In infants who have had the gall bladder anastomosed to the gastrointestinal tract we have, as yet no cases where stones have developed. It is too soon to state, and futile to predict, how many will form stones.

We believe that all infants with congenital atresia or stenosis of the bile ducts should be given the benefit of an exploratory operation. The diagnosis is relatively easy to establish and even though only 20 per cent or less will be found to have a condition that can be remedied by surgery it is worthwhile to make the attempt. The prognosis without operation, is uniformly fatal though these patients may live for a surprising number of months.

THOMAS H. LANKFORD

CONGENITAL ANOMALIES OF THE BILE DUCTS AND ADJACENT BLOOD VESSELS

IN no region of the human body are anomalies so common as in the bile ducts and adjacent blood vessels. It is therefore, impossible to present any pattern as the "normal" a composite of specimens least abnormal becomes the substitute for normal anatomy in this area. It is likewise true that in no region of the human body do anomalies result in so many serious accidents or consequences following surgery. Although carelessness and haste are vital causes of accidents resulting in stricture or absence of the common duct, the majority of these accidents would probably not occur if there were not such a great variation in anatomy.

In 39 cases of stricture of the common duct observed at Illinois Research Hospital over a 10 year period operative trauma was definitely identified as the cause of the stricture in 64 per cent. In an additional 20 per cent of cases jaundice developed 4 months to 5 years following cholecystectomy. Although inflammation of some type may be considered to be the cause of stenosis in this group, the fact remains that a gall bladder operation (cholecystectomy in every instance) preceded stricture formation. Other surgeons report similar figures relative to operative trauma as the etiologic factor (Cattell, 80 per cent, Walters 90 per cent). In 13 per cent of our series chronic sclerosing pancreatitis was the cause of the stricture. In only one patient (3 per cent) was there no history of operation preceding the stricture the cause of obstruction in this instance was an adhesion compressing the duct without actual fibrosis or damage to the duct wall. Causes of stricture not related to anomalies are ulceration of the duct by stone, chronic sclerosing pancreatitis neglected cholangitis

and abscess about the duct. Rarely indeed can choledochostomy be identified as the primary cause of stricture.

Extreme mobility of the common duct is a common cause of injury to this structure particularly if the cystic duct is short and wide. In this case traction on the gall bladder will make the cystic and common duct appear as one continuous structure (namely cystic duct). If more than average care is not exercised by the surgeon, he may thereby identify the common duct as cystic and ligate it, thus producing a complete obstruction of the common duct. On other occasions the cystic duct is long and lying against the common, as was noted in 20 to 25 per cent of cases by Eisen drath. Strenuous efforts to separate it from the common duct may result in so much damage to the latter structure that a stricture develops later. An accessory hepatic duct (noted by Flint in 15 per cent of cases) may give rise to stricture of the common duct by a mechanism not generally appreciated. If the accessory duct is cut unknowingly during cholecystectomy and not ligated, bile may accumulate around the common duct after operation and give rise to so much inflammation in the wall of the duct as to result in stricture formation at a later date. Section of an accessory hepatic duct is very apt to be unnoticed because flow of bile is commonly decreased to a marked degree during the operation thereby depriving the surgeon of the best method of detecting its division. Although abscess formation about the common duct is no doubt an important cause of stricture the author is convinced that accumulation of bile is probably a more common cause.

Arterial anomalies give rise to strictures of the common duct primarily because the duct is injured during the process of stopping hemorrhage from the injured anomalous vessel. In 15 per cent of cases (Flint), an accessory

cystic artery is present. After the surgeon has identified one cystic artery and ligated it, he is apt to proceed rapidly with the rest of the dissection and during this haste cut the other cystic artery. Division of either cystic artery will give rise to hemorrhage immediately adjacent to the common duct. If the surgeon should lose his presence of mind, and begin to stab blindly in the bloody field for the bleeding artery instead of controlling the hemorrhage by insertion of his index finger in the foramen of Winslow with compression of the hepatic artery against his thumb the common duct may be caught and ligated with the bleeding vessel. In 16 per cent of cases (Flint) the cystic artery is anterior to the common duct. The surgeon does not expect to find the artery in this location and during the process of incising the peritoneum and fibrous tissue over the common duct may cut the cystic artery. Control of the hemorrhage by improper means, as mentioned above, may likewise result in ligation of a portion of the common duct with the bleeding vessel. In 12 per cent of cases the right hepatic artery crosses to the right anterior to the common duct (Flint). In about 20 per cent of cases it proceeds from its normal position under the common duct to the right and anteriorly so that it parallels the cystic duct. In either of the two positions just mentioned it may be injured during dissection. In either case hemorrhage will be brisk. If the hemorrhage is not controlled skilfully and the bleeding point ligated carefully the common duct may be damaged. However in about 50 per cent of cases division and ligation of the right hepatic artery will result in death of the patient within a few days following operation. In these cases there will naturally be no opportunity for development

of a stricture. In 20 per cent of cases the gastroduodenal artery lies anterior to the common duct (Eisendrath). Although this vessel usually lies too far inferior to the area of dissection to be damaged, it might easily be injured if the surgeon should carelessly attempt to isolate the distal portion of the common duct. Hemorrhage would be very brisk and its control might result in injury to the wall of the common duct. In about 50 per cent of cases there is a small branch of the right hepatic or gastroduodenal artery in the anterior wall of the common duct. Although this artery is usually severed when the duct is opened for extraction of stones the resultant hemorrhage is rarely severe enough to result in significant damage to the duct during control of the bleeding joint.

About the only anomaly of the gall bladder giving rise to stricture of the common duct is an unusually large and pendulous Hartmann's pouch which lies on the common duct. Since adhesions are common in this area, it is obvious that damage may be inflicted on the common duct unless separation of the pouch from the common duct is carried out with extreme care (R. Graham).

In about 90 per cent of cases the portal vein bifurcates before entering the liver and in the remainder of cases enters the liver before bifurcation. Rarely is this anomaly related to injury or stricture of the common duct. The common hepatic duct bifurcates inside the liver in about 90 per cent of cases, and outside the liver in the remainder. This anomaly also is seldom related to injury to the duct itself but when the hepatic ducts join outside the liver and a stricture is present at this site the repair is greatly complicated by the anomalous bifurcation.

WALT WHITMAN — A CASE HISTORY

JOSIAH C. TRENT M.D., F.A.C.S., Durham North Carolina

WALT WHITMAN the Good Gray Poet the poet of democracy has been the center of many controversies since the publication of his *Leaves of Grass* in 1855. Although Walt was the prophet of the perfect body — "I sing the body electric" — the last 30 years of his life were dogged by ill health. He finally died 2 months before his 73rd birthday, a veritable pathological museum. Although there are many references to the state of Whitman's health particularly during the later period of his life, these are largely superficial and subjective. Examination of the available records, however, has allowed us to reconstruct, at least in outline, the tremendous struggles waged by one of our literary giants against physical and mental deterioration.

Walt Whitman was born at West Hills, Long Island, on May 31, 1819, the second of 9 children. His father, Walter Whitman, was a farmer and carpenter. When Walt was 4 years old the family moved to Brooklyn, then a village of about seven thousand inhabitants. He was educated in the common schools of Brooklyn and at 13 left school and began work as an errand boy in a doctor's office. Before reaching 15 he became an apprentice typesetter in the printing office of the *Long Island Patriot*. At 18 he tried teaching for a time in Long Island country schools, but in 1839 he turned again to printing, now as publisher of his own newspaper, *The Long Islander*, in Huntington. After a year or two he gave up the paper and returned to Brooklyn, where in 1841 he became editor briefly of the *Daily Aurora*, at the same time writing essays, stories, and poems for other newspapers and magazines. In 1842 he wrote a temperance novel, *Franklin Evans*. All these productions, whether prose or verse, show very little of the distinctive manner that was to mark Walt's

later writings; they show, in fact, very little merit of any kind.

With frequent vacations on rural Long Island, Whitman remained in Brooklyn and New York until early in 1848 when, having lost his post as editor of the *Brooklyn Eagle*, he set out for New Orleans to become editor of a newly established paper there. After a few months he returned to New York, where he continued to work as editor and writer and for a time as carpenter. In the spring of 1855, at the age of 36, at a Brooklyn printing house, he began to set type for a book of poems he had written and in July the first edition of *Leaves of Grass* appeared.

This amazing publication, utterly different from almost all he had earlier published, met for the most part with indifference or contempt in the literary world. Praise came chiefly from Emerson, who wrote in a letter to Whitman: "I find it the most extraordinary piece of wit and wisdom that America has yet contributed. I greet you at the beginning of a great career." The most truly appreciative reviews were written by Whitman himself.¹

Further editions of *Leaves of Grass* appeared in 1856 and in 1860, the latter from a Boston publishing house which collapsed with the coming of the Civil War. Walt's brother George enlisted promptly when the war began, while Walt stayed quietly in Brooklyn, writing poetry and visiting sick and disabled stage drivers in the hospitals. In December of 1862, when word came that George had been wounded, Walt left for the front. He found George nearly recovered but encountered many sick and helpless soldiers who needed his care, accordingly he stayed in Washington to

He published anonymously several reviews, one of which began: "An American bard at last! One of the roughs, large, proud, affectionate, eating, drinking, and breeding, his costume manly and free, his face sunburnt and bearded, his postures strong and erect, his voice bringing hope and prophecy to the generous races of young and old. If health were not his distinguishing attribute, this poet would be the very harlot of per sons" (18).

From the Division of Thoracic Surgery, Department of Surgery, Duke University School of Medicine and Duke Hospital, Durham, N. C.

Fig. Whitman in July 1854, at the age of 35

serve as volunteer nurse in the hospitals. This activity he carried on for 3 years, meanwhile holding various government positions and corresponding with New York papers. In the summer of 1863 when the hospital work appeared to be affecting his health he decreased somewhat the number and length of his visits, but by the end of the war he computed that he had made six hundred visits, seeing over eighty thousand sick and wounded soldiers.

After the war Whitman stayed on in Washington, working as a clerk in government offices and writing and publishing new editions of *Leaves of Grass*. In 1873 at the age of 54, he suffered a severe paralytic stroke. When he had partially recovered, he set out for the Jersey coast to avoid the summer heat of Washington, but broke down in Philadelphia and was taken to the home of his brother George in Camden. In this town he spent the greater part of his remaining years, at first with George, then in his own home on Mickle Street. Here he prepared further editions of the *Leaves*, the chief being those of 1881-1882 and 1891-1892. For long periods he was an invalid, confined to his room at times he was stronger and able to travel, to the West, to Canada, to Boston and New York. During these years his literary reputation, which had received its first real impetus

from his recognition by English literary lights in the sixties, grew ever wider though his poetry was not to receive general acceptance until the twentieth century. He had a small coterie of fervent admirers, among whom was the Canadian physician, Richard Maurice Bucke, who first visited Whitman in July 1877 and became one of the poet's closest friends as well as his principal medical adviser. After an illness of four months' duration, Whitman died on the 26th of March, 1892.

CASE SUMMARY

Family History (3)

Father Walter Whitman (1780-1855). Died after an exhausting illness of nearly 3 years from paralysis. His death was easy and unconscious.

Mother Lucina Van Velsor Whitman (1793-1873). Her letters to Walt in the sixties complain often of "lameness in the right arm, which was 'swollen and painful' (arthritis) also of 'blindness in my head,' 'nervousness and distress in my side' and 'bad coughing' (November 9, 1867). Cause of death unknown.

Brother Jesse Whitman (1808-1870). Had cardiovascular and central nervous system syphilis. In the last few years of his life became violent and was judged insane. He was confined to King's County Lunatic Asylum, Brooklyn, New York, here he died of "rupture of an aneurism."

Sister Mary Elizabeth Whitman Van Nostrand (1811-1899). Had arthritis. Cause of death unknown.

Sister Hannah Lucina Whitman Heyde (1813-1906). Was considered psychoneurotic. In 80 had mild paralytic stroke. Died in her 85th year of pulmonary edema, mitral insufficiency, valvular disease of the heart and chronic nephritis.

Infant Born April, 1805—died September 1815. Cause of death unknown.

Brother Andrew Jackson Whitman (1806-1863). Had chronic disease of the "throat and bronchia" which probably was tuberculosis. Walt lived in the same house with Andrew until shortly before he left for Washington in 1863.

Brother George Washington Whitman (1809-1904). In 1865 after George returned from the Army he was very sick for time with "lung fever." During 1865 he had "headaches and face was bloated for time." He also had rheumatic pains in his legs and hips. In 1899 George was sick and paralyzed.

Brother Thomas Jefferson Whitman (1815-1890). Died of "typhoid pneumonia (tuberculosis?)" Jeff married Martha E. Mitchell (1850) who died in 1873 of tuberculosis. Walt had close contact with Jeff and his life until he left for Washington.

Brother Edward Whitman (1815-1892). Eddie was ever normal. Apparently he had birth injury which left him with a crippled left hand and a paralyzed leg.

At the age of three he had scarlet fever which left severe after effects. He was also feeble-minded and an epileptic. He died in Blackwood Sanatorium, New Jersey of "valvular heart trouble."

Marital history

Walt never married although, according to his own statement, he had several illegitimate children (3, 14).

Past history

In his youth Walt presumably had no serious illnesses. He developed (1833-45) into a healthy strong youth.

(grew too fast though, was nearly as big as a man at 15 or 16) The years 1846, 47 and there along see me still in New York city working as writer and printer having my usual good health (16) His "usual good health" continued until about 1858 when he suffered from a "sunstroke"

(17) the details of this illness are unknown but it probably was the first of a subsequent series of minor strokes. He recovered apparently uneventfully and continued well except for colds. In April, 1863, he wrote his mother "I weigh about 200, and as to my face (so scarlet) and my beard and neck, they are terrible to behold. I fancy the reason I can do some good in the hospitals among the poor languishing and wounded boys, is, that I am so large and well—indeed like a great wild buffalo with much hair" (19)

Except for numerous colds accompanied by slight deafness, Walt remained fairly well until June 1863, when he complained of quite an attack of sore throat and distress in my head" (18) In July 1863, while assisting at the amputation of a gangrenous limb of a Virginia Union soldier to whom he was much attached, he sustained a cut of the right hand. His hand became inflamed and swollen, and red streaks ran up to the shoulder (10) The infection subsided in approximately 4 to 5 weeks but left him so extremely weak and debilitated that he was advised to desist from his hospital visits for a while. He improved rapidly and on August 11, 1863, was again able to write his mother that he felt better than he had in 6 weeks. About the wound in my hand and the inflammation, etc. It has thoroughly healed" (19) During the summer of 1863 Walt began to complain that the sun affected him, causing

aching and fulness on the head. (17) He resumed nursing the soldiers, however, and in January 1864, was "well and fat and weighed about 200" He continued to complain of "fullness of the head" particularly in hot weather and "spells of deathly faintness." He was again advised that he had "continued too long in the hospitals" and that he should not go "inside the hospitals for the present" (19) His spells continued with increasing frequency until finally in July 1864 he was "prostrated." Following this rather severe attack the "unconscious and perfect health" he "formerly had" was gone. It was his "first appearance in the character of a man not entirely well" (14) His spells persisted and in August and September 1869, he had an other severe attack which left him "prostrated and deathly weak," with little use of his limbs (13) He recovered satisfactorily and except for numerous severe colds remained well apparently until 1872 when he began to complain again of those "spells in the head" which had troubled him at intervals since 1864, and on January 24, 1873, he awoke to find himself paralyzed on the left side. He was placed under the care of Dr. W. B. Drinkard* of Washington, D. C., who gave him general supportive treatment, followed later by electric stimulation to his paralyzed side.

*William Beverly Drinkard (1822-1877) was born in Williamsburg, Virginia, the son of William R. Drinkard, Assistant Secretary and later acting Secretary of War under Buchanan. He received his education at Georgetown College, Washington, D. C. and the Lycée Impérial, Orleans, France. In November, 1860, he began the study of medicine at Paris. Here he assisted in Desmarres Clinic where he studied principally diseases of the eye. He studied also under such other eminent teachers of the time as Velpeau and Flourens. In July 1865, he went to London for several months and in the autumn of the same year returned to Washington where he entered the National Medical College from which he received the M. D. degree in March, 1866. In 1867 he was elected professor of anatomy at the National Medical College, a post he held until his premature death 5 years later. Although trained in ophthalmology he did not confine himself to this specialty but engaged in the general practice of medicine. He was one of the founders of Washington Children's Hospital. (8)

Fig. 2. Whitman at 44, in 1863.

After he had recovered sufficiently Walt started for the New Jersey shore to recuperate but broke down in Philadelphia and had to be taken to the Camden home of his brother George (10) Apparently Walt asked Dr. Drinkard to send his case report to Dr. Matthew Grier of Philadelphia, whom he saw several times.¹

Dr. W. B. Drinkard to Dr. Matthew Grier Washington City July 4, 1873. Autograph letter in the Trent Collection, Duke University Library (15) The letter reads as follows

My dear Doctor—

I am informed by M. Whitman, lately a patient of mine, now on a visit to Camden, that he intends to call himself of your counsel and treatment before returning to this city and he requests me to let you have a short statement of the history of his case up to the present time. It may be briefly stated thus. On the 3d of January—7 February—last M. W. previously in good health—was attacked with left hemiplegia, presenting all the symptoms of such conditions, though none of them very marked at any time. Speech was hardly appreciably impaired; facial distortion very slight; deviation of tongue just perceptible; left paretic extremity never wholly useless; left lower showing the paretic condition more than any other part or organ. Constipation slight at onset of attack, has required little attention subsequently.

Under the influence of rest, and such incidental treatment as was demanded from time to time, his general condition has slowly improved; locomotive power having, however been only imperfectly regained. His principal annoyance has been a recurrent headache, with tendency to nausea—never actually reaching the latter point (preceding ten words cancelled by Drinkard).

After subsidence of everything like active manifestations, I commenced, cautiously the use of the Induced Current—with Galiffe's battery—and continued it for a number of weeks, without apparent result, beyond a decided improvement in nutrition of the lower limb. When he was on the point of leaving, I sug-

Fig. 3. Whitman 1883, in 87

gested him the possible benefit to be derived from the use of the continuous current, and I think it is with reference to that more particularly that he wishes to consult you.

Dr. Whitman probably would not have habit of the testes & mental constitution. I think the most natural I have ever encountered and for those things he has all his life. Beyond this, the prognosis is, of course, of the stereotyped variety, fairly characteristic of such cases. He has occasionally taken potassium bromide & iodine bromide for his headaches for short time took the phosphates of iron, quinine & strychnine. Sometimes occasionally mild laxative—no other drugs that I recollect.

Hoping that you may be able to help Dr. Whitman in securing the bodily independence on which his usual mental hopefulness very much depends. I am, my dear Doctor,

Very truly Yours

Wm. B. DRYGDALE
Matthew J. Grier (1818-1900) as born in Philadelphia of Scotch Irish ancestry. He received his M.D. degree from the University of Pennsylvania in 1861 (8).

An incomplete manuscript note by Whitman (5) concerning visit to Dr. Grier is of interest here. June 27, 1874, visited Dr. Grier again today at 318 8th St. for consultation.

He reiterated his theory that any sufferings (later ones) come nearly altogether from gastric, stomachic, intestinal, non-cretory & catarrhs, causing flatulence, very great distension of the colon, all of passages, weight on valves, crowding & pressure on organs, (heart, lungs, etc.) and the very great distress & pain I have been under in breast left side & pit of stomach, & thence to my head, the last month. Advised me by all means to begin the use of an enema syringe (Fountain No. 1) (repeated for clysters)—was favorable to my evening walking—advised me to eat palea. 203—Kneading the bowel.

Under Dr. Grier's care, Walt improved gradually but in July 1883 had another attack which left him a year later "scarcely able to get up and down stairs" (3). It was at about this time that Dr. William Oeler at Dr. Bucke's request paid Walt a professional visit. The poet had recovered from his paralytic attack of 13 years before and had only slight residual weakness in his left leg. After careful examination Oeler told Walt that "the machine as in fairly good condition considering the length of time it had been on the road" (7).

Whitman's fairly frequent "sick spells" during the late seventies and early eighties culminated in June, 1888, in another severe paralytic stroke. Bucke, who happened to be in Philadelphia at the time, took Oeler with him to see Walt. They found him in bed, conscious but mentally confused and with the speech slightly blurred and indistinct. There was no fever and the pulse was good. He had had one or possibly two attacks of transient unconsciousness with difficulty in speaking such as now known are not uncommon with sclerosis of the arteries of the brain. For a week or more the condition looked doubtful, but he gradually improved and recovered without any permanent paralysis or loss of speech (7).

Although Walt appeared to have recovered from this attack satisfactorily, his course continued downward. In addition to his usual complaints of headache, lameness and inertia, for the first time he began to complain of "indigestion" and "bladder trouble" (see Review of Systems). On March 8, 1890, Dr. Bucke asked Dr. Daniel Longaker of Philadelphia to see Walt professionally. He found Walt an old man, who complained of constipation, lack of energy, "inertia," urinary frequency and urgency. His apparent age was greater than his real years. Remote memory was better than recent. He moved about awkwardly with the aid of his cane. Muscular strength in the upper extremities was normal, but sensation, as noted before, heart and lungs were in good condition. Little sclerosis of temporal or radial arteries.

Walt was treated expectantly, with massage, bathes, and catheterization, but continued in poor health until the onset of his present illness in December.

Review of Systems

Head. See Past History.

Eyes. Walt did not wear glasses and apparently had good vision until late in life.

The following notes (3) written by Dr. Grier indicate the treatment administered to Whitman:

R/Syr Calc lactophosph 3 /
Sug 14 teaspoonful after
breakfast & dinner
R 73 Grier
R/40 53
Sodae lactate 3p
Glycerine 3 T
M Sie Teaspoonful after
each meal
1-6 74 Grier

descending secondary currents of Electro-Magnetism to lower limbs—nose to the upper *trunk* each muscle separately. For the brain—Inverse constant current say about 6 to 10 Daniells cells from each sciatic N. t. sacrospinous region, and any higher under any circumstances. Every other day.

Dr. Longaker is still living in Philadelphia. In personal letter to the author Dr. Longaker remembers about Walt but cannot recall any details not already recorded in his article, "The Last Sickness and Death of Walt Whitman" (4).

Dr. Longaker showed Dr. Walt how to catheterize himself with soft rubber catheter. He expressed surprise that the operation was so easy and painless. No anodyne or cocaine was required, as is almost always necessary when this procedure is instituted" (4).

Ears Except for occasional episodes of deafness associated with severe colds, hearing was good.

Nose, pharynx, tonsils Frequent colds and sore throats see Past History.

Mouth Negative.

Teeth No record of his ever having visited a dentist.

Heart Negative.

Lungs During the years 1863 to 1865 while nursing the sick and wounded in Washington, Walt was constantly exposed to "lung diseases" (19). In April 1890, he had a severe attack of the grip which "sometimes almost strangled me" (3). In March 1891, he had some slight trouble in his upper respiratory tract which he called his "old attack of grip" (4). At no time did he complain of cough, dyspnea, wheezing, hemoptysis or chest pain.

Abdomen. See Present Illness.

Gastrointestinal. In December 1873 at the age of 54, Walt complained of "head troubles, & stomach troubles, & liver troubles—the doctor thinks the latter the worst & basis this time of all, or nearly all—head swimming, faintness, vomiting, etc." (14). On May 22, 1874, "my being disabled and want of exercise for 16 months, (and many other wants too) have saddled me with serious dyspepsia and what the doctor calls gastric catarrh, very obstinate causing me really more suffering and pain than my paralysis." In December 1875 "these troubles" (feeling of death and dizziness) "in the doctor's opinion" are from a very serious and obstinate liver affection—not from head, lungs, heart. (13). March, 1876 "I still have this baffling obstinate, apparently chronic affection of the stomachic apparatus and liver. appetite sufficiently good, eat only very plain food. digestion tolerable." (5). Jan. 27, 1891 "head, belly and bladder matters all in a bad way." March 16, 1891 "Obstinate long-continued horrible indigestion." (3). May 23, 1891 "The fiendish indigestion block continued" (14). Walt complained of obstinate constipation until onset of present illness. There is no mention of jaundice, characteristic gall-bladder pain or intolerance to fatty foods.

Genitourinary. Dec. 3, 1888 "My physical trouble has veer'd quite entirely lately, or (more truly) added to and is now that senile botheration from prostate or enlarged or inflamed gland (bladder business, diabetes) or other worse or less form of ailment. Dr. Osler was here this afternoon and is to bring over a surgeon on the 5th P.M., for more concise examination." It has resulted the last four nights in quite no sleep. Dec. 4 "The gland suffering or whatever it is (the distressing recurrent stricture like spasms, at first from three to ten minutes almost continuously the last five days and nights) has let up." (3). Jan. 27, 91 "head, belly and bladder matters all in a bad way." Mar. 91 "Frequency 20 times a day, nocturia, dysuria (See Past History).

Venereal. Negative.

Neuromuscular. See Past History.

Extremities. See Past History.

Personal habits. In person Whitman was large and tall, above six feet. "He was in no sense a muscular man, an athlete. His body though superb was curiously the body of a child. One saw this in its form, in its pink color and in the delicate texture of the skin. He took little interest in feats of strength, or in athletic sports. He walked with a slow rolling gait indeed moved slowly in all ways but always had an air of infinite leisure" (1).

His usual weight was 200 pounds or more, but at the onset of the present illness was only 140 pounds. Although temperate in the use of alcohol, he was not a total abstainer. He was inclined to eat excessively. He did not use tobacco.

Fig. 4. Whitman with his nurse Warren Fritzinger in July 1890.

Present Illness (4, 6)

Walt was in his usual health until the afternoon of December 17, 1891, when he had a severe shaking chill followed by a rise in temperature (102°). This was accompanied by slight hoarseness and a cough productive of mucopurulent sputum. There was complete loss of appetite and marked prostration.

Course of illness. Dr. Longaker saw the patient 24 hours after the onset of the illness. At that time he found areas of dullness over both lungs, particularly on the right. The following day the third of his illness, the areas of dullness had increased, especially over the right lung. It was thought he had a widely diffused bronchopneumonia. The lungs were poorly aerated and there were "hints of heart failure." On the fourth day Dr. Alexander McAlister of Camden was called in consultation so that a doctor could be immediately available in case of a sudden change for the worse. Walt showed no improvement and a tracheal rattle and cyanosis were noted. On December 22nd irregularity of the pulse developed. The following day the irregularity was more marked. Somnolency and cyanosis continued. Dec. 24. Extensive involvement of the left lung was found with the right practically useless. There was marked cyanosis, labored respirations, and a rapid weak, and irregular pulse. Dec. 26 Walt appeared semi-conscious but could be roused easily. The heart was still

*On his next visit Osler brought with him Dr. Wharton there is no record of their joint opinion on the case (11).

irregular and intermittent. Dec. 7. A careful examination of the chest revealed some resonance on percussion and faint breath sounds. Bilaterally present. The left side was more impaired than the right. The respiratory movements were rapid and entire. Abdominal movements expected on continued. The cough, prominent from the beginning, greatly accentuated. He went to bed on his right side. There was little if any fever. Weight loss. On Dec. 11, December 20th, when it became clear that the illness was to be protracted, a professional nurse, Mrs. Elizabeth K. Lee, was engaged.

Slight improvement occurred and continued, and 1 January, normal pulse and respiration in rate were established.

During the previous 30 days, the pulse was 100, 110, 120, 130, 140, 150, 160, 170, 180, 190, 200, 210, 220, 230, 240, 250, 260, 270, 280, 290, 300, 310, 320, 330, 340, 350, 360, 370, 380, 390, 400, 410, 420, 430, 440, 450, 460, 470, 480, 490, 500, 510, 520, 530, 540, 550, 560, 570, 580, 590, 600, 610, 620, 630, 640, 650, 660, 670, 680, 690, 700, 710, 720, 730, 740, 750, 760, 770, 780, 790, 800, 810, 820, 830, 840, 850, 860, 870, 880, 890, 900, 910, 920, 930, 940, 950, 960, 970, 980, 990, 1000.

On March 1, the patient was found dead. The body was found in the bed, with the head turned to the left. The face was pale, and the eyes were closed. The mouth was slightly open, and the tongue was protruding. The hands and feet were cold, and the skin was mottled. The chest was rigid, and the lungs were consolidated. The heart was enlarged, and the liver and spleen were also enlarged. The kidneys were normal in size and position. The bladder was full, and the rectum was empty. The stomach was empty, and the intestines were normal. The overall condition of the body was one of extreme weakness and exhaustion.

On March 1, the patient was found dead. The body was found in the bed, with the head turned to the left. The face was pale, and the eyes were closed. The mouth was slightly open, and the tongue was protruding. The hands and feet were cold, and the skin was mottled. The chest was rigid, and the lungs were consolidated. The heart was enlarged, and the liver and spleen were also enlarged. The kidneys were normal in size and position. The bladder was full, and the rectum was empty. The stomach was empty, and the intestines were normal. The overall condition of the body was one of extreme weakness and exhaustion.

Autopsy

The autopsy was performed by Dr. Longaker (at my request) on the 11th of March. The following are the notes of the post-mortem performed in the presence of Mr. W. H. Whitman, March 11, 1884. The body was found in the bed, with the head turned to the left. The face was pale, and the eyes were closed. The mouth was slightly open, and the tongue was protruding. The hands and feet were cold, and the skin was mottled. The chest was rigid, and the lungs were consolidated. The heart was enlarged, and the liver and spleen were also enlarged. The kidneys were normal in size and position. The bladder was full, and the rectum was empty. The stomach was empty, and the intestines were normal. The overall condition of the body was one of extreme weakness and exhaustion.

Mrs. D. N. Whitman, housekeeper, much opposed to the post-mortem examination of Mr. Whitman. (Of course, she had no legal right to prevent Mrs. George Whitman from having a post-mortem on her husband.) I consented to the post-mortem on the 11th of March. The body was found in the bed, with the head turned to the left. The face was pale, and the eyes were closed. The mouth was slightly open, and the tongue was protruding. The hands and feet were cold, and the skin was mottled. The chest was rigid, and the lungs were consolidated. The heart was enlarged, and the liver and spleen were also enlarged. The kidneys were normal in size and position. The bladder was full, and the rectum was empty. The stomach was empty, and the intestines were normal. The overall condition of the body was one of extreme weakness and exhaustion.

The American Anthropometric Society was not invited to the post-mortem. The body was found in the bed, with the head turned to the left. The face was pale, and the eyes were closed. The mouth was slightly open, and the tongue was protruding. The hands and feet were cold, and the skin was mottled. The chest was rigid, and the lungs were consolidated. The heart was enlarged, and the liver and spleen were also enlarged. The kidneys were normal in size and position. The bladder was full, and the rectum was empty. The stomach was empty, and the intestines were normal. The overall condition of the body was one of extreme weakness and exhaustion.

has been organized for the express purpose of studying high type brains, it tends to first photograph the external surfaces, and then make a cast of the entire brain. After this, careful microscopic studies may be made by competent observers.

Both the head and the brain were remarkably well formed and symmetrical. The scalp was thin, and practically bald. The hair on the head was fine and dark. The eyebrows were thin, and the eyelashes were fine. The nose was straight, and the lips were thin. The mouth was slightly open, and the tongue was protruding. The hands and feet were cold, and the skin was mottled. The chest was rigid, and the lungs were consolidated. The heart was enlarged, and the liver and spleen were also enlarged. The kidneys were normal in size and position. The bladder was full, and the rectum was empty. The stomach was empty, and the intestines were normal. The overall condition of the body was one of extreme weakness and exhaustion.

The head was well formed, and the brain was well developed. The skull was thin, and the brain was large. The cerebellum was well developed, and the cerebrum was also well developed. The brain was covered by a thin layer of meninges, and the blood vessels were normal. The overall condition of the brain was one of extreme weakness and exhaustion.

The heart was enlarged, and the lungs were consolidated. The liver and spleen were also enlarged. The kidneys were normal in size and position. The bladder was full, and the rectum was empty. The stomach was empty, and the intestines were normal. The overall condition of the body was one of extreme weakness and exhaustion.

The lungs were consolidated, and the heart was enlarged. The liver and spleen were also enlarged. The kidneys were normal in size and position. The bladder was full, and the rectum was empty. The stomach was empty, and the intestines were normal. The overall condition of the body was one of extreme weakness and exhaustion.

The findings were: Harmon Allen, Francis Xavier Dennis, Joseph Leahy, W. H. Whitman, and Charles J. Dennis. The body was found in the bed, with the head turned to the left. The face was pale, and the eyes were closed. The mouth was slightly open, and the tongue was protruding. The hands and feet were cold, and the skin was mottled. The chest was rigid, and the lungs were consolidated. The heart was enlarged, and the liver and spleen were also enlarged. The kidneys were normal in size and position. The bladder was full, and the rectum was empty. The stomach was empty, and the intestines were normal. The overall condition of the body was one of extreme weakness and exhaustion.

The brain of W. H. Whitman, together with the fat removed from the body, was found in the bed. The body was found in the bed, with the head turned to the left. The face was pale, and the eyes were closed. The mouth was slightly open, and the tongue was protruding. The hands and feet were cold, and the skin was mottled. The chest was rigid, and the lungs were consolidated. The heart was enlarged, and the liver and spleen were also enlarged. The kidneys were normal in size and position. The bladder was full, and the rectum was empty. The stomach was empty, and the intestines were normal. The overall condition of the body was one of extreme weakness and exhaustion.

The pleurae were found to be diseased in the membrane of the lungs. The body was found in the bed, with the head turned to the left. The face was pale, and the eyes were closed. The mouth was slightly open, and the tongue was protruding. The hands and feet were cold, and the skin was mottled. The chest was rigid, and the lungs were consolidated. The heart was enlarged, and the liver and spleen were also enlarged. The kidneys were normal in size and position. The bladder was full, and the rectum was empty. The stomach was empty, and the intestines were normal. The overall condition of the body was one of extreme weakness and exhaustion.

breathing purposes. The upper and middle lobes were consolidated and firmly bound down to the pleura. There were about four ounces of fluid in the cavity. Large tubercular nodules and areas of catarrhal pneumonia were everywhere to be found. Those portions of the lung not tubercular were markedly emphysematous, this being especially marked at the free edges of the lung.

The spleen was soft and weighed about eight ounces, the capsule thickened and fibrous on section pulpy. It was matted down to the diaphragm and showed only peritonitis and peri-splenitis. Numerous tubercles occupied this region extending to the anterior wall of the stomach and to all of the neighboring viscera. The diaphragm was pushed downward by the fluid.

The kidneys were surrounded by a mass of fat. The left suprarenal capsule was tubercular and contained a cyst the size of a pigeon's egg. In this was found a darkish fluid. The capsule strips readily; the kidney weighed about six and one half ounces, and showed some parenchymatous change. The kidney substances were soft, red, and swollen and somewhat granular. The right kidney was a little the smaller and the better of the two.

The liver was about normal in size, though fatty and contained an extra fissure near the center. Some tubercles were observed.

A huge gall stone almost entirely occupied a rather small gall bladder to which it was firmly adherent. The outer surface of the stone was covered with a whitish deposit.

The pancreas was hemorrhagic. The common ducts were but very slightly atheromatous.

Over the whole of the mesentery especially in its lower portion were hundreds of minute tubercles varying in size from that of a fine needle-point to the head of a good sized pin. These whitish points were surrounded by a hemorrhagic base. The serous surface of the intestines was injected and dotted with tubercles. The bladder was empty and the walls thickened. The prostate was enlarged. The rectum was swollen and filled with semi fluid feces. A few hardened masses were found in the transverse colon. The stomach was small. The vermiform appendix was two inches long and patulous, containing two small hardened fecal masses of an irregular outline. The sigmoid flexure was unusually long.

The above macroscopic lesions of the various organs were confirmed by microscopic sections.

It would seem very probable that the extensive adhesion of the dura mater to the calvarium was due to an old sun-stroke.

"The cause of death was pleurisy of the left side, consolidation of the right lung, general miliary tuberculous and parenchymatous nephritis. There was also found a fatty liver gallstone a cyst in the adrenal, tubercular abscesses, involving the bones, and pachymeningitis."

COMMENT

The autopsy is exasperatingly incomplete and from the available facts it is difficult to reconstruct the exact sequence of events which led to Walt's death. However it is sufficiently inclusive to allow us to revise the diagnosis to conform with our present-day concepts of pathology.

Did Whitman really have tuberculosis? Could he have had cancer of the prostate with terminal spread or a primary cancer of the lung? Tuberculosis was well recognized by 1892¹⁴ however and

¹⁴Koch work on the tubercle bacillus was done in 1882.

Figure 5 Whitman at 73 1891

since the autopsy was performed by some of the best American pathologists of the day we are reasonably safe in accepting their diagnosis.

Judging from the extensive involvement of the right lung the upper and middle lobes were consolidated and firmly bound to the pleura, the tuberculous process was of long duration probably years. Unfortunately no mention is made of the left lung other than that it was completely pressed against the mediastinum. The apparent long duration of the pulmonary lesion with no antecedent history of cough, dyspnea, chest pain or hemoptysis is nothing short of remarkable. Walt was exposed to members of the family with tuberculosis for several years before he left for Washington in 1862 at the age of 43 but it was precisely at this time that he was proclaiming his excellent health. During his Washington hospital days also he must have been exposed to much tuberculosis among the soldiers. However in his frequent references to his illnesses of this period there is no mention of pulmonary compli-

cations. The tuberculous pleural effusion on the left probably had been present some months before his terminal illness and could have been secondary to extension through the parietal pleura of the chest wall abscess or the rupture of a small tuberculous node.

At the onset of his last illness the infected pleural fluid, which could have been responsible for the sudden chill and fever must have ruptured into a bronchus, for there was profuse expectoration of mucopurulent sputum at the onset, something entirely new for Walt. This profuse expectoration which was greatly accentuated when he lay on his right side persisted until his death. Sufficient drainage of the left chest through the bronchus must have occurred to produce the slight symptomatic improvement noted early in the course of his last illness. The fluid on the left was not diagnosed antemortem because the doctors did not wish to subject Walt to the discomfort of a complete examination. The presence of a bronchopleural communication on the left is further borne out by Dr. Longaker's examination of the anterior surface of the chest on March 11th when he found "impairment of resonance on right—good on left, indicating that there was air in the left pleural space and not in the lung since the autopsy showed the lung to be collapsed against the mediastinum.

The tuberculous abscesses of the sternum, rib and chest wall and foot were old but their exact duration is difficult to estimate.

Numerous tubercles occupied the area around the spleen extending to the anterior wall of the stomach and all neighboring viscera including the left adrenal gland. No tubercles were found in the splenic pulp and only a few were observed in the liver. The mesentery and intestine particularly the lower portion were covered with minute tubercles. This certainly is not the picture of a military spread via the blood stream but rather that of a direct dissemination probably from an old focus around the spleen a lesion which may have been of the same vintage as the abscesses described above and which undoubtedly accounted for the hiccup and severe pain in his left side.

The left adrenal cyst indicated an old process and may have been in part responsible for the "lassitude and inertia" Walt complained of for many years. No mention was made of the right adrenal gland.

Since careful examination of the brain was not carried out we have no record of old areas of destruction which might have been present, but we do have the autopsy findings of extensive

cerebral atrophy. In spite of marked wasting of the brain described at the postmortem examination, Walt's mind continued active and keen to the last although his memory had begun to fail.

His long-standing symptoms of indigestion, nausea and constipation can be attributed to the chronic cholecystitis and cholelithiasis.

His urinary symptoms arose from the urethral obstruction secondary to hypertrophy of the prostate.

Did Walt have hypertension or perhaps a labile blood pressure secondary to vasospasm? This, of course, would have been an antemortem diagnosis if his blood pressure could have been measured.¹⁴ In favor of such a condition are his ruddy complexion, frequent severe headaches and feeling of fullness in the head and the numerous slight to severe cerebral insults suffered after 1858. However in hypertension of such long standing we should expect more advanced arteriosclerosis and cardiac hypertrophy.

Our revised and final diagnosis should read, then Pulmonary tuberculosis far advanced, right atelectasis of left lung, tuberculous empyema, left bronchopleural fistula, left disseminated abdominal tuberculosis, tuberculous abscesses of sternum fifth rib and left foot, cyst of left adrenal gland, chronic cholecystitis and cholelithiasis, cerebral atrophy, cerebral arteriosclerosis benign prostatic hypertrophy, pulmonary emphysema, cloudy swelling of kidneys, history of hypertension (?).

In an age of psychiatry no discussion of Whitman's medical history would be complete without some mention of that very controversial subject of his sexuality. Was he homosexual? At this late date an unassailable answer is unlikely although after a study of his life, personality habits, and writings, one fact stands out clearly by no standards could Whitman's attitudes and behavior toward sex be considered "normal." Yet the charge of homosexuality has never been proved. John Burroughs, a friend of long standing described Walt as in "no sense a muscular man an athlete. His body though superb, was curiously the body of a child. One saw this in its form, in its pink color and in the delicate texture of the skin." (1) Perhaps this is the real clue to the personality of the man who embraced all mankind, man and woman alike. Could he have been eunuchoid?

¹⁴Last revision of *Lancet*, 30-32.

¹⁵Sphygmomanometry was introduced in the late 19th century.

REVIEWS OF NEW BOOKS

IN the opening chapter of *Erkrankungen des uropoelischen Systems und der Prostata durch Störung der Blutdringung* by Hutter the author favors humoral pathology of living tissues over the cellular pathology teaching of Virchow. In his opinion humoral pathology gives a more rational explanation of normal and abnormal body cells. Increase and growth of tissues result from substances brought to it by the blood stream. In malignancies for instance there is a battle between the blood ingredients going to normal and tumor cells. Many writers are quoted endorsing the new views of disease and pathological cellular changes. Hutter contends that laboratory examinations and procedures while important, can never give an accurate clinical estimate of the patient's health and prognosis.

In prostatic hypertrophy the author states that there is a hormonal imbalance with the male component predominating. Following surgery of the prostate Hutter believes that foreign hemostatic bodies and ligatures used to control bleeding promote wound infection and secondary hemorrhage. The wound reunion of the urethra and bladder with primary bladder closure tends to shorten the morbidity and wound healing. The prostatic bed can produce its own hemostasis and should not be interfered with too much by the surgeon.

Urinary calculi were more frequently noted in immobilized injured and wounded soldiers. Many autopsies and reports are quoted giving the incidence of urinary calculi in amputees and severely wounded. There was a much higher mortality in soldiers following nephrectomy for tuberculosis (25%) than in peacetime civilian practice (no deaths in 200 nephrectomies). The high mortality is attributed to war dislocations and shock.

The circulation in the presence of renal lesions (pyelonephritis, early arteriosclerosis, war nephritis, poisons) may be improved by removing the overacting vasoconstrictors (decapsulation).

The lesser grades of nephropathosis seldom cause hydronephrosis and infection. Mild cases should be treated conservatively. Advanced cases respond to surgery and nephropexy.

There is an interesting discussion on scoliosis, kyphoscoliosis, lordosis, and resulting impairment of renal function. The difference in renal and uterine displacements on the convex and concave sides are carefully noted and illustrated with drawings and roentgenograms.

This compend is a good postwar review of urologic subjects and problems. Infectious urology is not in-

cluded. There is no mention of the newer therapeutic agents as penicillin or streptomycin.

LEANDER W. RITA

THE first edition of *Fundamentals of Psychiatry* by Edward A. Strecker appeared in 1942. In the fourth edition the text has been revised once again. The author has added a chapter on psychosomatic psychiatry as well as two suggested nomenclatures for classification. There are chapters also on etiology, methods of examination and symptoms organic and toxic psychoses, functional psychoses and psychoneuroses, psychiatry and war and psychiatric nursing, and finally there is a glossary and an index. The style is clear, terse, firm and often distinguished by dry wit. Diagrams are offered to represent the author's conceptions for elementary students. His extensive experience is often evidenced and his grasp of the somatic aspects and accompaniments of mental disease. His general approach agrees with that of Adolph Meyer well known as psychobiology (cf. p. 34). The name of Freud appears only twice when he speaks of Freud's "hypothesis of the Id" (p. 172) and of Freud's conception of neurasthenia (p. 238). However the influence of Freud can be traced on numerous pages when the author gives his own views, for example on conversion hysteria and on paranoia and paranoid conditions. "In waking life and in sleep," he states (p. 206) "in its conscious, subconscious and unconscious components there is unceasing mental activity. Like some other topics, treatment as a rule is little more than outlined in this book. Nevertheless, the beginner in psychiatry and the doctor in other fields will find it most useful in acquainting him with the status of present day psychiatry."

LEONARD JACOBSON

THE great decline in the incidence and mortality from communicable disease in the United States during the past twenty five years and the introduction of chemotherapy and antibiotic therapy has reduced the number of specialists skilled in the diagnosis and treatment of communicable disease. In most instances these experts are principally found in cities of great population where the greatest number of cases occur. However, diagnosis, adequate modern treatment, and reporting of cases promptly to health authorities to increase speedy control are still a major responsibility of the general practitioner.

The need for authoritative reference based on up-to-date experience is now more essential than ever for the complete battle against the communicable diseases.

FUNDAMENTALS OF PSYCHIATRY By Edward A. Strecker, M.D., Sc.D., M.D. L.H.D., F.A.C.P. 4th rev. ed. Philadelphia, London, and Montreal J. B. Lippincott Co., 647

ERKRANKUNGEN DES UROPOELISCHEN SYSTEMS UND DER PROSTATA DURCH STÖRUNG DER BLUTDRINGUNG. By Professor Dr. Karl Hutter. Vienna, Austria: Wilhelms Mandrich, 1947.

The second edition of *Handbook of Communicable Diseases* by Dr. Franklin H. Top presents in a clear, concise, colorful and illustrative pattern the present day knowledge about each communicable disease which the family physician is called upon for consultation.

The 14 new chapters dealing with specific diseases and discussed by collaborating authorities enrich the value of the second edition of *Handbook of Communicable Diseases*. Newer problems such as primary atypical pneumonia, revision of nursing care leprosy, management of communicable diseases in hospital, malaria, epidemic keratoconjunctivitis, leptospiral jaundice, ringworm of the scalp constitute additional information elaborated upon in the second edition.

This book deserves not only the intensive study of every medical student but also should be part of the personal library of every general practitioner.

E. A. PRZCZK

A SERVICEABLE aid to the medical student and a convenient source of graphic material for the postgraduate is presented in Professor Jamieson's *Illustrations of Regional Anatomy*. The seven small volumes contain an ample series of pictures of gross anatomical structures. The booklets however have no accompanying text, contain no directions designed to guide a dissector. The legends are of the briefest order. The current edition and its predecessor contain an index.

The illustrations are grouped in compact volumes in each of which the loose leaves are fitted on pillars from these the sheets are easily removable for rearrangement in any sequence momentarily convenient to the reader. The pages are printed on one side only the paper stock is unusually good. The 320 plates of illustrations cover the anatomy of the several subdivisions of the body: central nervous system, head and neck, abdomen, pelvis, thorax, upper limb and lower limb. The head and neck are allotted the largest number of figures, the thorax the smallest number.

The brain is extensively illustrated, basal nuclei, motor and sensory areas are indicated diagrammatically as are also the principal tracts, commissures, etc., blood vessels, cerebral ventricles and choroid plexuses are all presented in very arresting coloration.

The anatomical features of the head and neck are illustrated by drawings which include entire dissection fields, layer by layer dissections of individual sense organs, diagrams of nerve plexuses and of transverse and sagittal sections taken at crucial levels. Some of the figures might be baffling to a

novice since they do not indicate what has been excluded or which layers have been removed to bring into view the stratum which the figure represents. Others lose value by being so diagrammatic that they merely suggest but do not closely resemble the particular group of structures as they appear in a dissected human body.

The booklet on the abdomen contains ingenious illustrations of the abdominal muscles and the inguinal canal, but some of them in being utterly diagrammatic, sacrifice anatomical clarity to attain schematic vividness. The treatment of the inguinal region, mesenteries, blood vessels, kidneys and suprarenals is highly conventional, the figures resemble museum models rather than dissections. The schematic drawings of the abdominal layers take considerable liberty with the true constitution of the parietal lamellae and laminae; they do record the common variations which are important in laparotomy and in hernioplasty.

In the volume on the pelvis and perineum, color is again profusely but often helpfully used. The author's order of plates is seemingly rather haphazard for a division of anatomy in which a knowledge of serial succession is of fundamental surgical importance. While the layers of the pelvic and urogenital diaphragms are shown in schematic clearness, they are not portrayed accurately. The relations of the pelvic viscera to their ligamentous, fascial and diaphragmatic supports would be of little use in training critical students for the practice of gynecology, urology or proctology.

In the set of plates which depict the anatomy of the thorax, the schematic method is utilized to greater advantage, since much of the important anatomy of the thoracic cage and of its visceral, vascular and nervous contents may be taught from transverse and sagittal sections and from surface projections of organs.

In the sections on the upper and lower extremities the figures which show the plaques of muscular attachment to the skeletal elements are fundamentally similar to those found in the standard textbooks, atlases and manuals of gross anatomy. Here the order is the logical one of successive layers from cutaneous nerves, superficial veins, and fascial cleavages through progressively deeper layers of muscle. In the simpler figures for example those dealing with the synovial sheaths of the hand and foot the schematic plan is utilized to great advantage but when the same device is employed to show the tendons, nerves, vessels and muscles, the collection of transected structures forms a somewhat overpowering assemblage.

The colors employed in the illustrations seem upon first examination to be needlessly garish. However the reader soon becomes accustomed to their chromatic strength and learns to use the colors as so many signals.

Considered as a whole *Illustrations of Regional Anatomy* is a useful adjunct to the student's regular anatomical library. It treats of the kind of anatomy

HANDBOOK OF COMMUNICABLE DISEASES. Franklin H. Top, A.B., M.D., M.P.H., F.A.C.P. 2nd ed. St. Louis: The C. V. Mosby Co., 1947.

ILLUSTRATIONS OF REGIONAL ANATOMY. By E. B. Jamieson, M.D. Section I—Central Nervous System, Section II—Head and Neck, Section III—Abdomen, Section IV—Pelvis, Section V—Thorax, Section VI—Upper Limb, Section VII—Lower Limb. 7th ed. Edinburgh: E. & J. S. Livingstone, 1947. Baltimore: The Williams & Wilkins Co., 1947.

which is customarily presented in charts. Its graphic character, going beyond the limit set in the standard type of illustration, allows the set of books to function as a link between the regular atlas which the student uses at the dissection table and the black-board drawings which so commonly enliven lectures in gross anatomy. For the familiar compendia, digests and summarizing handbooks of anatomy these abundantly illustrated volumes would serve as ideal companions.

BERRY ANSON

THE ninth revision of the popular textbook, the Ballenger *Diseases of the Nose, Throat and Ear* remains one of the best introductions to otolaryngology for the student and practitioner. It is easily readable, clearly written for the most part, and its numerous illustrations are well selected and graphic. A wide amount of information is given which in the

NOSE, THROAT AND EAR. By William Lincola Ballenger M.D. F.A.C.S. and Howard Charles Ballenger M.D. F.A.C.S. Assisted by John Jacob Ballenger B.S. 11th ed. Philadelphia Lea & Febiger 1917

space allotted requires a somewhat dogmatic presentation. moot points are on the whole adequately discussed and errors are few.

Considerable emphasis has been placed on operative procedures. While this may give the student a somewhat biased view it helps make the book valuable for reference as well as for an undergraduate text. From description and illustration, operative techniques are easily grasped. The method of describing operative procedures on the basis of historical development gives the student an understanding not otherwise attainable in many instances. In others it leads to the retention of perhaps an unnecessary amount of deadwood.

Latest advances in the specialty are well covered. A new chapter has been added on headaches and neuralgias of the face and head and up to date revisions are given on the labyrinth, endoscopy and the operative relief of laryngeal paralysis by authorities in those fields. The format is good, the paper and printing excellent and the volume maintains its previous high standing.

CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

ARTHUR W ALLEN *Boston President*
DALLAS B PHEMISTER, *Chicago, President Elect*

PRELIMINARY PROGRAM FOR 1948 CLINICAL CONGRESS THE BILTMORE HOTEL, LOS ANGELES, OCTOBER 18 TO 22, 1948

PLANS are proceeding for the program of the thirty fourth Clinical Congress of the American College of Surgeons which will be held in Los Angeles at the Biltmore Hotel from October 18 to 22 1948

A preliminary schedule of clinics, preceded by a list of the hospitals which will participate and the names of the representatives who are responsible for the program at each hospital, was published in the June issue. Twenty-five hospitals have so far indicated a desire to participate and they will arrange their programs to cover subjects in general surgery obstetrics and gynecology fractures, or thoracic surgery thoracic surgery neurosurgery genitourinary surgery and ophthalmology and otorhinolaryngology During the Congress Daily Clinical Bulletins will be issued which will give the final clinical program

It is expected that arrangements for telecasting operations from one or more of the hospitals will soon be ready for announcement. The use of television is especially desirable after the exceedingly successful demonstration of its teaching value at the Clinical Congress in New York last year

The usual varied and comprehensive program of meetings at the headquarters hotel is planned. The opening session will be a General Assembly for both surgeons and hospital personnel on Monday morning Scientific sessions, official meetings, and hospital conferences will follow during the five day Congress. In addition to meeting rooms in the Biltmore Hotel the Biltmore Theater and the spacious Philharmonic Auditorium across the street from the hotel will be used for the larger audiences The capacity of the Philharmonic Auditorium is 2,700 and that of the Biltmore Theater about 1,700

PRESIDENTIAL MEETING

The opening evening session of the Clinical Congress will be devoted to the Presidential Meeting at which the officers-elect, consisting of Dr Dallas B Phemister of Chicago as president, Dr Howard A Patterson of New York as first vice president, and Dr Carl H McCaskey of Indianapolis as second vice president will be installed. Dr Arthur W Allen of Boston, outgoing president and vice chairman of the Board of Regents, will preside and will deliver the Presidential Address. The third Martin Memorial Lecture will be delivered by Dr Clarence Crafoord Professor of Surgery University of Stockholm.

CONVOCATION

The annual Convocation will be held on the final evening Friday The formal initiation ceremonies and the presentation of the Fellowship Address by Dr L A Du Bridge, President California Institute of Technology Pasadena, will constitute the program Dr Du Bridge's subject will be 'The Physicist Meets the Doctor'

EVENING SCIENTIFIC SESSIONS—GENERAL SURGERY

'Malignant Lesions of the Thyroid Gland' will be the subject of the Tuesday evening general surgery symposium 'Pathology' will be discussed by Dr Frank W Foote of New York Aberrant Thyroid by Dr Brien T King of Seattle 'Malignancy in Nodular Goiter' by Dr Warren H Cole of Chicago and 'Radioactive Iodine in the Treatment of Thyroid Diseases Including Cancer' by Dr Myron Prinzmetal Los Angeles

Endometriosis will be the subject for the Wednesday evening general surgery symposium. Significance of Endometriosis will be discussed

by Dr Joe V Meigs of Boston "Surgical Procedures Involved in the Treatment of Endometriosis" by Dr Virgil S. Counsellor of Rochester Minnesota. A third paper will be presented on "Theories and Medical Treatment of Endometriosis. The annual Fracture Oration will also be presented at the Wednesday evening session.

Surgery of the Heart and Great Vessels will be the subject of the Thursday evening general surgery symposium. "Surgical Treatment of Pulmonic Stenosis" will be discussed by Dr Alfred Blalock of Baltimore "The Surgical Treatment of Constrictive Pericarditis" by Dr Emile F Holman of San Francisco "The Surgery of Patent Ductus Arteriosus" by Dr John C. Jones of Los Angeles and "Treatment of Coarctation of the Aorta" by Dr Robert E Gross, Boston.

EVENING SCIENTIFIC SESSIONS—OPHTHALMOLOGY

The preliminary program for the Tuesday evening Ophthalmology session includes the following subjects "Tumors of the Eyelids and the Conjunctiva" by Dr Michael J Hogan of San Francisco Partial Keratectomy by Dr George L. Kilgore of San Diego and the third paper will probably be on "Studies of the Cytology of Conjunctival Exudates.

The Wednesday evening program will be devoted to a panel discussion on the subject, "Neoplasms of the Orbit and Nasal Accessory Sinuses and will be participated in jointly by ophthalmologists and otorhinolaryngologists.

The program for the Thursday evening Ophthalmology session includes the following subjects "Retinal Detachment," by Dr Dohrmann K. Pischel of San Francisco "The Use of Retrobulbar Alcohol Injection for Ocular Pain," by Dr Alfred E. Maumenee of Baltimore and the third paper is not yet definitely selected.

EVENING SCIENTIFIC SESSIONS OTORHINOLARYNGOLOGY

The preliminary program for the Tuesday evening Otorhinolaryngology session includes four subjects "Effects of Streptomycin on Eighth Nerve Function" by Dr Page Northington of Oakland "Anatomical Considerations in Ear Surgery" by Dr J. Brown Farrior of Tampa. A third paper will be on "Suspension Laryngoscopy" and there will be a fourth for which a definite title has not yet been determined.

The Wednesday evening program as stated under "Ophthalmology" will be on the subject, "Neoplasms of the Orbit and Nasal Accessory Sinuses," and will be a joint session with the ophthalmologists.

The program for the Thursday evening Otorhinolaryngology session includes the following four subjects "Tumors of the Nasopharynx," by Dr Harry C. Rosenberger of Cleveland "Modern Management of Oro-Antral Fistula," by Dr Richard Thomas Barton of Beverly Hills "Present Day Status of Fenestration Surgery" by Dr Leighton F. Johnson of Boston and a fourth paper will probably be on "Laryngeal Malnecy

GENERAL SURGERY PANEL DISCUSSIONS

General surgery panel discussions will be held on Monday Tuesday and Wednesday afternoons, from 1:30 to 3:00 and from 3:30 to 5:00 o'clock, and on Thursday afternoon from 3:30 to 5:00. The early session on Monday will be on "Acute Renal Failure in Surgical Patients," with Dr Frederick A. Collier of Ann Arbor as moderator and the late session on "Tumors of the Mouth, Jaw and Face," with Dr Gordon B. New of Rochester Minnesota, as the moderator. The early session on Tuesday will be on "Low Lying Malignant Lesions of the Bowel," with Dr. Fred W. Rankin of Lexington, Kentucky as moderator and the late session on "Evaluation of Liver Function in Relation to Surgery" with Dr Nathan A. Womack, Iowa City as moderator. The early session on Wednesday will be on "Peripheral Arterial Disease" with Dr Alton Ochsner of New Orleans as moderator and at the late session "Ulcerative Colitis" will be discussed with Dr Henry W. Cave of New York as moderator. The Thursday session will be concerning "Isotopes in Surgery" with Dr George M. Curtis of Columbus as moderator.

OPHTHALMOLOGY PANEL DISCUSSIONS

Panel discussions in ophthalmology will be held Tuesday Wednesday and Thursday mornings from 9:00 to 10:30 o'clock. The Tuesday subject will be "Surgical Management of (1) Acute Inflammatory Glaucoma (2) Chronic Simple Glaucoma (3) Congenital Glaucoma," with Dr A. Ray Irvine of Los Angeles as the moderator. The Wednesday subject will be "Congenital Cataract" with Dr Otto Barkan of San Francisco as moderator. The Thursday subject will be "Surgery of the Oblique Muscles" and Dr C. Allen Dickey of San Francisco will act as the moderator.

OTORHINOLARYNGOLOGY PANEL DISCUSSIONS

Panel discussions in otorhinolaryngology will be held Tuesday Wednesday and Thursday mornings from 10:45 to 12:15 o'clock. The Tuesday

subject will be 'Rehabilitation of the Hard of Hearing' with Dr. Walter P. Work of San Francisco as moderator. The Wednesday subject will be 'The Preparation of the Surgical Patient and Postoperative Care' with Dr. Colby Hall of Los Angeles as moderator. The Thursday subject for discussion will be 'Diseases of the Esophagus' with Dr. Alden H. Miller of Los Angeles as moderator.

SPECIALTY PANEL DISCUSSIONS

Specialty panel discussions will be held on Friday afternoon from 1:30 to 3:00 and from 3:15 to 4:45 o'clock, as follows:

Urology—Moderator, Dr. Reed M. Nesbit, Ann Arbor

1:30 to 3:00 p.m.—'The Clinical Management of Branched Renal Calculi.'

3:15 to 4:45 p.m.—'Present Day Management of Urinary Tract Infections.'

Orthopedic Surgery—Moderator, Dr. John C. Wilson, Los Angeles

1:30 to 3:00 p.m.—'Mechanical Derangements of the Knee Joint.'

3:15 to 4:45 p.m.—'Fractures about the Hip.'

Thoracic Surgery—Moderator, Dr. Frank S. Dole, Los Angeles

1:30 to 3:00 p.m.—'Diagnosis and Surgical Treatment by Pulmonary Resection for Carcinoma, Bronchiectasis, and Tuberculosis.'

3:15 to 4:45 p.m.—'Surgery of the Esophagus.'

Plastic Surgery—Moderator, Dr. Truman G. Blocker, Jr., Galveston

1:30 to 3:00 p.m.—'Congenital Facial Deformities.'

3:15 to 4:45 p.m.—'Burn Contractures of the Extremities.'

Gynecology and Obstetrics—Moderator, Dr. John C. Burch, Nashville

1:30 to 3:00 p.m.—'Hysterectomy: Physiological Considerations—Indications.'

3:15 to 4:45 p.m.—'Hysterectomy: Technical Considerations—Complications.'

Neurological Surgery—Moderator, Dr. Howard C. Naffziger, San Francisco

1:30 to 4:45 p.m.—'Cerebral Angiography'

a. Anatomical Interpretations of Angiography

b. Characteristic Patterns of Angiography in Brain Tumors.

c. Angiography of Circulatory Lesions and Their Treatment.'

d. 'Technique and Materials.'

FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

The Forum on Fundamental Surgical Problems, one of the most popular features of Clinical Congresses during the past few years, will be held on Tuesday through Friday mornings in two sections meeting concurrently. Brief reports of original clinical and experimental observations relating to the broad aspects of surgery and the surgical specialties will be presented under the general direction of Dr. Owen H. Wangensteen, chairman of the committee. Forum on Fundamental Surgical Problems.

HOSPITAL CONFERENCES

The opening meeting of the twenty-seventh Hospital Standardization Conference will constitute the first formal session of the Clinical Congress, and will be a General Assembly for both surgeons and hospital representatives. Dr. Arthur W. Allen of Boston, President of the College, will preside. The hospital conferences will continue on Monday afternoon with sessions following on Tuesday, Wednesday and Thursday mornings, afternoons and evenings.

Hospital trustees, administrators, heads of the various hospital departments and their personnel, nursing groups, and many other persons directly or indirectly concerned about hospital progress, are invited to participate in the discussions at the hospital conferences, at which leaders in the hospital field are the speakers and the moderators. The meetings will include formal sessions, panel discussions, round table conferences, symposia and forums.

A meeting which is always of great interest to hospital administrators and members of medical staffs in hospitals as well as to surgeons is the Symposium on Graduate Training in Surgery which is scheduled for Thursday afternoon after the Annual Meeting of Fellows.

COMMITTEE ON ARRANGEMENTS

The Committee on Arrangements for the Clinical Congress in Los Angeles has been well organized and is actively functioning. The membership follows:

General Committee

Donald G. Tollefson, M.D., F.A.C.S., *Chairman*
Hugh T. Jones, M.D., F.A.C.S., *Vice-Chairman*
Harold Lincoln Thompson, M.D., F.A.C.S., *Secretary-Treasurer*
Gilbert J. Thomas, M.D., F.A.C.S., *Regent of the College*
E. Vincent Askey, M.D., F.A.C.S.
Max W. Bay, M.D., F.A.C.S.
J. MacKendie Brown, M.D., F.A.C.S.
Lawrence Chaffin, M.D., F.A.C.S.
A. Ray Irvine, M.D., F.A.C.S.

Maurice Kahn, M.D. F.A.C.S.
 W. E. MacPherson, M.D.
 B. O. Raulston, M.D.
 Louis J. Regan, M.D.
 Carl Kusche, M.D., F.A.C.S.
 Stafford Warren, M.D.

Committee for the Southern California Chapter

Ray B. McCarty, M.D. F.A.C.S., Riverside
 Meredith G. Beaver, M.D. F.A.C.S., Redlands
 Clarence E. Rees, M.D. F.A.C.S., San Diego
 Carl G. Johnson, M.D. F.A.C.S., Long Beach
 James H. Saint, M.D. F.A.C.S., Santa Barbara

Hospital Committee

The members of the hospital committee are listed with the list of hospitals participating in the clinical program which preceded the preliminary schedule of hospital clinics in the June issue.

MEDICAL MOTION PICTURES

An appreciated feature of the Clinical Congress will again be the showing of medical motion pictures each day. The latest available pictures on surgery and related subjects will be presented. Special showings will be arranged of medical motion pictures in the fields of ophthalmology and otolaryngology. Both sound and silent films will be shown, all of which will have been approved by the Committee on Motion Pictures. Some of the newer medical motion pictures now under production will be shown.

TECHNICAL AND SCIENTIFIC EXHIBITIONS

The Technical and Scientific Exhibits will occupy the Ballroom foyer, the Renaissance Room, and the Galleria of the Biltmore Hotel, according to present plans. Leading manufacturers of surgical instruments, x-ray apparatus, sterilizers, operating room lights, ligatures, dressings, hospital apparatus and supplies of all kinds, and pharmaceuticals, and publishers of medical books will be represented.

ADVANCE REGISTRATION

Surgeons who wish to attend the Congress should register in advance. Under a new plan, advance registration will greatly expedite the procedure of registering.

No registration fee will be charged Fellows whose dues are paid to December 31, 1947. For endorsed Junior and Senior Candidates, the fee will be \$5.00. Non-Fellows who after individual consideration are permitted to register will pay a fee of \$10.00.

No registration fee will be required of initiates of the class of 1948.

HOTEL RESERVATIONS

It is desirable to make hotel reservations as early as possible because of the shortage of hotel rooms that prevails in Los Angeles as well as in other cities. In making these, communications should be addressed to the Los Angeles Convention and Visitors' Bureau, care of the Los Angeles Chamber of Commerce, stating that you will be attending the Clinical Congress of the American College of Surgeons. All hotel reservations for the Clinical Congress are to clear through this Bureau. No correspondence should be sent directly to the hotels. A form for reservations was enclosed in the letter recently sent to Fellows. Choice of hotels may be designated. The hotels in Los Angeles require a deposit in advance.

There follows the list of member hotels, Convention and Visitors' Bureau, Los Angeles Chamber of Commerce.

LOS ANGELES HOTELS

	Rates (as of May 5, 1948)	
	Double	Twin

COLLECTIVE REVIEW

THE CAUSES AND POSSIBLE REDUCTION OF OPERATIVE MORTALITY IN GERIATRIC SURGERY WITH AN ANALYSIS OF 100 CONSECUTIVE AUTOPSY RECORDS

LOUIS CARP M.D., F.A.C.S. New York New York

'Grow old along with me!
The best is yet to be,
The last of life for which the first was made.
Rabbi Ben Ezra Browning

WHEN Marcus Tullius Cicero (106-43 B.C.) wrote his delightful and philosophical *De Senectute*, he little dreamed that in the middle of the twentieth century the medical profession and an interested public would pool their facilities to help explain the aging process and that they would seek methods to increase longevity and to insure a happier and healthier existence during the declining years. With an inspiring optimism, Cicero relished the activities of old age. He indicated his intolerance of those who grumbled about advancing years when he quoted the venerable Cato as saying in his dialogue with his two younger disciples Scipio and Laelius the very period (old age) which at a distance is every man's warmest wish to attain no sooner arrives than it is equally the object of his lamentations, and I know not any season of life that is passed more agreeably than the learned leisure of a virtuous old age. He dismissed the sex problem by quoting the nonagenarian Sophocles who when asked if he engaged in amorous commerce with the fair sex exclaimed "Heaven forbid! and glad am I to have made my escape from the tyranny of so impial, New York, New York.

Read before The New York Surgical Society November 26, 1947

perous a passion. He was a firm believer in the immortality of the soul. Among the simple rules that he formulated for the prolongation and enjoyment of life were discretion in eating habits, mental activity, occupation on the soil and participation in sports. Some of these rules were erroneously arrived at by generalizing from the particular. Surgery was not mentioned. He left that for those who were to follow.

A previous communication (10) reports a statistical analysis of 2,558 collected cases including our series. All of the patients were over the age of 60 and had had major operative procedures including emergency surgery. They showed a mortality rate of 13.1 per cent. Our own experience in a municipal hospital was based on 450 major surgical operations, 13 per cent of which were of an emergency nature. The over-all mortality was 22.6 per cent in patients who represented an extreme substandard risk. All of these figures are not prohibitive when we consider that the major portion of the patients were cared for in periods when the more recent advances in chemotherapy, diagnostic aids, early ambulation, anesthesia, nutrition and parenteral and vitamin therapy were not available. In our cases the clinical impression was given that the major causes of operative death within 1 month after operation were heart failure, bronchopneumonia or both accompanied by pulmonary edema. This impression was fortified by a review of 55 autopsy records of patients between the seventh and tenth decades. It is the purpose of

this article to discuss in more detail a larger number of our autopsy findings covering the period from 1939 to 1947 and then relate to the causes of operative mortality in geniatric surgery and also to discuss briefly various possible salient prophylactic measures against such mortality. In making certain observations in this study it must be recognized that there are some variable and intangible factors in the condition of these patients in the light of which positive conclusions are difficult to establish.

LIFE SPAN AND MORTALITY RATE

The life span is increasing. Extraordinary progress has been made during the past 35 years in conserving life despite the adverse effects of two world wars and a major economic depression. The expectation of life at birth rose from 46.2 years in 1911 and 1912 to 65 years in 1945, a gain of 18.3 years (36). Between the ages of 65 and 74 the decrease in mortality from the years between 1911 and 1915 to those between 1941 and 1945 was 29.1 per cent for white males, 27.9 per cent for colored males, 36.7 per cent for white females, and 25.8 per cent for colored females. It is estimated (37) that those who are 65 years and older will constitute 9.1 per cent of the population in 1960 and 11.0 per cent in 1980. Table I (41) is self explanatory and demonstrates clearly that the leading causes of death are diseases which attack people of the older age groups. These observations present a challenge which the surgeon must meet by playing an increasingly important role in geriatrics.

OPERATIVE MORTALITY DEFINED

What constitutes an operative mortality? The answer to this question necessarily gives rise to varying opinions. Basically the time element involved in a death after operative therapy should be the important factor. Balanced against this is life span without operation. It is not justifiable to speak of a mortality 3 months postoperative if it is estimated that the patient with diminished homeostases would have lived no longer nor less than 3 months without operation. For practical purposes, it has been our custom to speak of operative mortalities in the aged if they occur within 1 month after operation. Generally during this period the patient feels the maximum effect of a technical procedure and it is at this time that the surgeon uses his greatest effort to tide him over. No either wins or loses.

THE CAUSES OF OPERATIVE MORTALITY

It is fair to state that in our hospital, as in other hospitals, efficiency was diminished during the war years because of insufficient and, at times, inexperienced personnel to carry out routine procedures. The shortage of physicians, nurses, attendants, and laboratory workers caused curtailment in service and inadequate observation for the records. The increased and multiple demands on those on the home front necessarily resulted in less supervision by those in senior positions. It may be assumed these conditions had some bearing on adverse mortality rates during this period.

Systemic pathological changes in the aged are usually so varied and marked that unless there is an obvious cause of death it may be difficult even after autopsy to state the principal cause of operative death, i.e., the lesion which has killed the patient. Concomitant disease of the heart, blood vessels, kidneys, lung, liver or brain, with accompanying metabolic disturbance may confound the pathological picture to such an extent that it is almost impossible to attribute the cause of operative death to a specific pathological diagnosis. The problem is amplified if there is evidence of an acute myocardial infarction, cerebral hemorrhage, primary tuberculosis, severe bilateral pneumonitis, multiple liver abscesses, pancreatic necrosis, general peritonitis or carcinoma with multiple metastases. Too frequently autopsy protocols show a long list of pathological findings which the most expert pathologist may find difficult to evaluate in terms of the principal cause of death. Therefore after a mortality conference in which there is an exhibition of organs and tissue sections from autopsy material the clinician may be left in the dark concerning the principal cause of

death The contributing causes are usually more evident. One patient had a celiotomy in the course of which an inoperable carcinoma of the stomach was found. Two days later he died and autopsy also showed a diffuse bilateral bronchopneumonia. Did the carcinoma or the pneumonia kill him? In order to avoid academic discussion we have inclined to the belief that he would have lived longer without operation and that the bronchopneumonia was the primary cause of death.

A correlation of clinical impressions and autopsy findings in the older age groups has clearly demonstrated that death has too often resulted from unsuspected pathologic conditions which are in no way related to the condition for which the patient had surgical therapy. Chief among these are pneumonia, cardiac dilatation, gastric and intestinal dilatation, thrombosis, and infection in vital organs.

In order to minimize the possibilities of error in determining the cause of operative death because of the clinical findings, 100 consecutive autopsy protocols of patients above the age of 60 who died within 1 month after operation were analyzed. The results of the analysis have been striking and instructive. The contributing causes of death common to all the records were varying degrees of arteriosclerosis, valvular defects, coronary atherosclerosis and myocardial, renal, and liver damage. These contributing factors cannot be underestimated since any one of them or any combination may be sufficient cause to help unbalance the scales against a patient whose homeostasis is already delicate and whose margin of safety is hazardous. It is in this respect especially that there is such a marked difference between the young and old in tolerance to operative therapy. There were 66 males and 34 females who were subjected to autopsy. The oldest patient was 91 years of age. The average age was 72 years for both sexes. Table II shows the distribution of autopsies by systems or organs together with the principal and contributory causes of death. Table III gives an analysis of the causes of death. Instructive observations from these autopsies will be incorporated in various pertinent sections of this article. Other observations can be briefly summarized as follows:

Bronchopneumonia and heart failure with accompanying pulmonary edema equally caused a little more than half of the total deaths.

Deaths following gastrointestinal operations were caused in most instances by peritonitis the result of existing perforation at the time of operation or subsequent leakage of the suture lines. Palliative gastroenterostomy for carcinoma of the

stomach would better have been done as far away from the neoplasm as possible and preferably with a Murphy button. Suture lines are then unnecessary and greater operative speed lessens the chance of cardiopulmonary death. Two patients with carcinoma of the colon came to operation too late. They had obstruction perforation with peritonitis and general metastases. Peritoneal metastases predisposed to peritonitis, even when only an exploratory celiotomy was performed. All the cases of intestinal obstruction were unduly delayed for operative therapy. The patients were vulnerable to mesenteric vessel damage, gangrene of the bowel and peritonitis.

Acute abdominal conditions in the aged are frequently difficult to diagnose. One patient had an appendectomy in the presence of a diverticulitis of the sigmoid.

Among the 20 patients who had operations on the genitourinary tract there were 13 with pyelonephritis. Eight in this group succumbed. The remainder died of cardiopulmonary complications which included bronchopneumonia and occlusion of the coronary artery.

The major cause of death in operations for biliary tract disease was bronchopneumonia. Two patients died of occlusion of the coronary artery. One of these should not have been subjected to operation because of a recent coronary attack. He died during the induction of anesthesia. One patient died of gastrointestinal hemorrhage. In this instance common duct obstruction with jaundice was too prolonged.

Patients with mid thigh amputations for arteriosclerotic gangrene died mostly from massive thrombosis in the intra abdominal or intrathoracic vessels, whereas amputees for diabetic gangrene died of systemic complications such as bronchopneumonia, sepsis or pulmonary edema.

Bronchopneumonia or embolism took its toll of those who had operative fixation for fracture of the neck of the femur.

Sepsis predominated as a cause of death in pyarthrosis.

Among the contributory causes of death, unsuspected pyelonephritis, metastatic carcinoma, bronchopneumonia, coronary occlusion and pulmonary tuberculosis were impressive.

Emergency surgery. Conduct W. Cutler Jr. presented a paper from our service before The American Surgical Association in March, 1947 on his observations in 188 consecutive emergency procedures of many types in people over the age of 60 (average age 74). The mortality rate was 44 per cent. These cases occurred between the years 1939 and 1946 and represented patients who were

extremely bad risks, old and senile poverty stricken afflicted with chronic and degenerative disease and those with nutritional deficiencies. Most of these patients would have succumbed without operation and this was their only chance for survival. Frequently before admission to the surgical service, there was prostration and an attempt at conservative treatment, so that the surgical risk was increased in many patients. There were a number of understandable reasons for the delay in seeking surgical help in some of the cases. Because of many medical complications, the clinical picture might have been confusing so that a rapid and accurate diagnosis became difficult in the presence of a surgical emergency. The impact of such an emergency frequently caused a rapid deterioration of these very sick people in a very few hours, so that when they reached the surgeon their condition was desperate. Further there is a natural inclination on the part of the physician to delay an operative procedure in old, sick, and feeble patients until it becomes inescapable. In order to hasten the prospects for operative relief additional delay for ideal preoperative preparation was at times precluded especially in intestinal obstruction, biliary tract disease, and spreading infection or gangrene.

A comparison of the relative mortalities in emergency and nonemergency operations showed that the expected mortality rate will be about two and one fourth times greater in emergency than in nonemergency procedures. This figure was arrived at by comparing the 44 per cent mortality in emergency operations mentioned with the 19.4 per cent mortality in nonemergency operations, which were calculated from the statistics from our service mentioned in paragraph two.

Shock. Frequently operative mortality which has been ascribed to shock is caused by fundamental pathologic lesions which cannot be seen without autopsy. A discussion of the irreversible shock syndrome as a cause of mortality is pur-

posely avoided because, after an analysis of the autopsy protocols, pathological diagnoses were noted which could adequately explain death. This does not mean that the complex mechanism of shock does not contribute to such exits, especially when there are damaged vital organs, chiefly the kidney and liver.

PREOPERATIVE PROPHYLAXIS AGAINST MORTALITY

Establishment of diagnosis. Inasmuch as physiological reserve in the aged is diminished, it is extremely important to establish a reasonably certain diagnosis before therapy is attempted. The planning of a surgical procedure then becomes more accurate so that the patient receives the indicated preoperative preparation and is spared the trials of technical fumbling, unnecessary surgical trauma, incorrect or multiple incisions, and lengthy or exploratory operations. Older people do not stand these as well as those who are younger.

The role of heat and humidity. The surgical risk in the aged is increased when there is operative intervention on hot and humid days. McConnell *et al.* concluded that saturated still air at 90°F is the upper limit of the environment in which man is able to maintain heat equilibrium. The proper dissipation of heat in patients who undergo major surgery is essential. This is true especially in those who live in a temperate climate and who, because of their basic metabolism, may be peculiarly sensitive to heat and humidity. The ability to control normal body temperature has been found deficient in those with disease of the nervous system (19). Leucocytes are increased in those who have prolonged exposure to high temperature, and it is possible that an exhaustion of this defense mechanism might result (19). The syndrome recognized as "postoperative heat stroke" can be avoided if elective procedures are postponed from a hot to a cooler day and if the blood chloride and fluid loss following excessive perspiration are controlled by appropriate measures.

There are a number of standard accessory therapies with necessary variations, which depend upon the clinical condition and chemical status of the patient. Among these are infusions with blood or its substitutes, with amino acids, or with glucose and saline solution. In addition, there are available nasal tube feeding and oral feeding of palatable chocolate-flavored amino acids, hydrolysates, skimmed milk powder (Varco) vitamins, liver extract, or folic acid when indicated.

The control of diabetes The question of the control of sugar metabolism in surgical diabetes is answered by two schools of thought. One school permits diabetic patients to "spill over" 50 grams or more of glucose in the urine daily provided that enough protamine insulin is used to maintain good nutrition and to prevent ketosis and/or such clinical symptoms of diabetes as polyuria and thirst. The other school uses every available method to control the diabetes so that the blood sugar approaches normalcy. In diabetes there is a greater incidence of degenerative diseases, infection gangrene poor wound healing, and acidosis. A controlled diet and the use of insulin, therefore, are indicated to help tide over the surgical diabetic and spare him a continued hyperglycemia with its harmful end results. There is one contraindication to this program. Some diabetic patients react to a sudden lowering of the blood sugar to a comparatively normal figure by attacks of angina pectoris which are precipitated by coronary artery spasm or coronary artery occlusion. Generally speaking however the use of insulin, glucose, water and salt are enough to glycogenize and hydrate the patient.

Cardiac status: presbycordia and digitalis therapy All the autopsies indicated that there were varying degrees of cardiac valvular defects and/or valvulitis with cardiac dilatation or hypertrophy. There were also constant findings of varying degrees of coronary sclerosis with myocardial fibrosis, and often old and infrequently (5 per cent) recent, myocardial infarcts. These observations and electrocardiographic and physical findings confirmed the fact that the myocardium in the aged is weakened and its reserve is impaired. It is therefore to be expected as pointed out by Dry that the mechanisms of cardiac deaths are likely to be congestive heart failure from exhaustion of the cardiac reserve, sudden coronary occlusion ventricular dysfunction as a result of interference with the conduction system peripheral circulatory collapse, or massive pulmonary embolism. A note of optimism was sounded by Ochaner when he said, "I think that it would be unfortunate should surgeons receive the impression that patients

suffering from heart disease are especially safe. I believe that they are safe because they are considered especially unsafe.

When a prospective life-saving operation is necessary angina pectoris of organic origin does not contraindicate a technical procedure. The almost universal presence of coronary artery disease in our autopsy findings and the small incidence of acute coronary artery occlusion seem to support this statement. Other investigators have come to the same conclusion. Blumgart *et al.* reported that there were no operative deaths in 25 patients who had complete ablation of the thyroid gland for angina pectoris. Brumm *et al.* found that of 257 patients who had coronary artery disease and who underwent major surgical procedures, 22 had healed myocardial infarcts and the remainder had angina pectoris. Only 4.3 per cent of this group had cardiac deaths and 7 of the 11 deaths could be attributed to coronary thrombosis. Master and his coworkers studied a total of 625 attacks of coronary artery occlusion which were substantiated by autopsy and/or clinical and electrocardiographic findings. Two-thirds of the patients were past the age of 60 and 5.6 per cent of the total number had the coronary occlusion within 3 weeks after an operation. It is possible that some of these patients might have had attacks without an operation, since they all had disease of the coronary artery.

When the beneficial effects of digitalis on a weakened and dilated heart are considered, the direct action on the muscle usually takes precedence over the inhibitory action on the vagus, so that the relaxation of the ventricle during diastole is less than before the administration of the drug. The various heart irregularities, whatever their causes, are usually controlled by digitalis. In view of these facts, it has become our practice to prepare elderly patients for operation by digitalization, unless there is some contraindication to its use, such as heart block. There are some who differ with this concept, especially those who fear the thromboplastic properties of digitalis, which have been shown experimentally and clinically by Macht and by Minsale *et al.* However an increased cardiac reserve not only minimizes the chances of heart failure, but helps to prevent stasis in the pulmonary circuit. Stasis ordinarily predisposes to pulmonary congestion and offers a locus minoris resistentiae for pneumonia and pulmonary edema. Indeed most terminal pneumonias may be ascribed to this mechanism.

Embarrassment of the circulatory system by overloading it with fluids and by increased intra-abdominal pressure with its harmful effect on

cardiac action are to be avoided. Generally subdued activity out of bed several days prior to operation may diminish slowing of the blood stream and consequent predisposition to thrombosis.

Chemotherapy It is generally conceded that the control of intercurrent infections has reduced the morbidity and mortality of the degenerative diseases which accompany the aging process. The least toxic of the antibiotic agents is penicillin and this is tolerated particularly well by the aged. Indiscriminate use of penicillin has been severely criticized. However pneumonia, pyelonephritis, and secondary infection are so commonly present as postoperative complications with their concurrent deleterious effects on the blood forming organs that the routine prophylactic preoperative use of penicillin for 48 hours before major geriatric surgery seems justifiable even in cases which have no obvious infection. The same program is continued for 48 hours after operation.

In preparation for operations on the intestinal tract, the comparative elimination of pathogenic bacteria in the intestinal flora by streptomycin and by sulfonamides such as sulfathiazole and succinylsulfathiazole has done much to minimize infection and peritonitis in spite of putrefaction promoted by a high protein diet. The classical methods of minimizing such putrefaction should not be overlooked namely, bowel cleansing by saline cathartics and by enemas or colon irrigations.

Psychological approach The elderly patient frequently has fixed ideas about the living the dead and the future. He may accept an imminent surgical experience with a calm and fatalistic philosophy. On the other hand, he may be negativistic and resistant, with resulting lack of co-operation. It is this kind of patient who is ready to give up and "lay down and die." He must therefore be conditioned to a more hopeful outlook by a radiant, confident, and optimistic bedside approach and by the demonstration of a keen interest in his welfare. The surgeon can resort to harmless compromises and judicious, constructive flattery. In interviews with ministers in the various religious groups have proved their value in preoperative mental conditioning.

Timing of operation. The clinical eye and surgical judgment must decide the timing and the amount of operative therapy. Conservatism at the wrong time, such as procrastination or operative therapy which is too late, may be one of the greatest causes of operative death. This is especially applicable to infections, gangrene, malignancy and the obstruction in various systems. Prolonged "work-ups" when a diagnosis has been established with reasonable certainty very often

TABLE III.—CAUSES OF DEATH

	Principal causes	Important contributory causes
Bronchopneumonia	28	10
Cardiac dilatation	27	3
Pulmonary edema		
Peritonitis	18	1
Thrombosis and embolism	7	2
Sepsis	7	1
Pyelonephritis	6	15
Coronary occlusion	3	2
Anaesthesia	3	—

turn the delicate scales against the patient. Stasis promotes infection and disturbed metabolic, fluid, electrolyte and nitrogen balance. Obstruction in the biliary tract, the urinary tract, the gastrointestinal system and the pulmonary tree call for as prompt surgical intervention as is compatible with adequate and safe preparation of the patient for operation. By way of illustration the rate of operative mortality in obstructive lesions in the biliary tract is heightened by cholemia and cholangitis caused by unnecessary delay. Analogous situations arise in other systems. Early relief of obstruction is mandatory. Preliminary decompression of the gastrointestinal and urinary tracts by one of the various tube devices can be life-saving and produce a smoother postoperative course.

OPERATIVE PROPHYLAXIS AGAINST MORTALITY

Anesthesia Proper anesthesia is one of the major factors which contributes to a safer operative and postoperative period. The skilled anesthesiologist, armed with the newer concepts in chemistry, physiology and pharmacology as they relate to surgery, usually determines the type of anesthesia after analysis of the hospital record and after consultation with the surgeon. Measures to alleviate excitement immediately before operation are especially indicated in the aged. The choice and dosage of preoperative sedation are selective. As a general rule, minimal sedation is advisable. Smooth induction of anesthesia in appropriate anesthesia rooms is highly desirable. The new experience may be grotesque and frightening to patients if induction is accomplished in the operating room. The clash of instruments the hiss of sterilizers men and women in white, and a disturbing word which is dropped inadvertently may all contribute to unnecessary excitement.

An evaluation of anesthetics in geniatric surgery has been made in a previous communication (10). The success of local anesthesia is dependent upon its technical application and upon the patient selected. For example local anesthesia is highly satisfactory in procedures for decompression of abdominal viscera, the repair of inguinal hernias, and the excision of superficial growths. The use of novocaine (1 per cent) without the addition of adrenalin, is preferred because the adrenalin tends to make the patient excitable and nervous. It is also better to detect and to tie bleeders than to promote temporary blood vessel constriction by adrenalin.

Spinal anesthesia with its various refinements, is very helpful in prolonged lower intra-abdominal procedures and in amputation of the lower extremities. It is contraindicated in patients with organic disease of the central nervous system and in those with deformity or arthritis of the spine. It is also contraindicated in those with marked hypertension or nephritis, in whom the accompanying drop in blood pressure may cause an acute suppression of renal function.

All inhalation anesthetics should be accompanied by ample oxygenation. Cyclopropane seems preferable to all other inhalants. It is less toxic and makes for the smoothest postoperative recovery. Ethylene has been discontinued because of its explosive risk and its tendency to cause anoxia. Ether administered by the open-drop method is still a good supplemental and stimulating anesthetic. Nitrous oxide and oxygen is useful for short anesthetics.

Avertin anesthesia in the aged should be used with a great deal of caution. It is contraindicated in those with diminished cardiac reserve, liver disease, chronic pulmonary conditions, and in those who are in shock. If the patient does badly during operation, it is difficult to prevent further action of avertin and he may just "sleep away."

The intravenous use of sodium pentothal for short operative procedures is gaining favor.

Curare as an adjunct to the lighter anesthetics is gradually becoming more acceptable, especially in upper abdominal procedures. The pure alkaloid yields an agent which produces complete muscle relaxation by interruption of the normal action of acetylcholine at the myoneural junction. This eliminates bronchospasm.

A stomach empty of food during operation helps to guard against vomiting with its attendant risk of aspiration, choking atelectasis, or aspiration or lipid pneumonia. Suction of the nasopharynx to dispose of excess mucus should be routine.

Some of our concepts in crymal anesthesia need revision. We have recently noted that in the average case there is no more shock after amputation with a well selected general anesthetic than with crymal anesthesia. Three of 4 patients in our autopsy protocols who had mid thigh amputations for arteriosclerotic gangrene died of massive thrombosis in the large vessels. All these patients were operated upon under crymal anesthesia with the tourniquet technique. We must suspect, therefore that the tourniquet by causing unnecessary trauma to blood vessels already diseased, may cause extensive thrombosis. It seems logical that in amputations for all peripheral vascular disease the tourniquet is contraindicated. Crymal anesthesia without the tourniquet technique, is indicated for patients who are extremely bad risks and for those who have spreading infection.

Technique In geniatric surgery especially technical procedures which are too late, too little or too much may be great predisposing factors to mortality. When the head and hands work together when there is a minimum of lost motion and tissue trauma, and when there is meticulous attention to hemostasis, the precipitation of irreversible shock and of postoperative storm are unlikely. An unskillful and time-consuming cholecystostomy certainly involves more risk than a skillful and rapid cholecystectomy. Indicated stage operations reduce mortality. Disembowelment in abdominal procedures, especially in intestinal obstruction, should be guarded against as far as possible. Through-and-through abdominal sutures can be life-saving when a lengthy operation produces an imminent hazard. Retention sutures in celiotomies, careful approximation of tissue planes, and nonabsorbable suture material lessen the possibility of wound disruption.

Amputation stumps on the operating table have created a perplexing problem to many as a result of recent war directives and war experience. For practical purposes, the Surgeon General's Office deemed it advisable to adopt a standard method of amputation leaving the stumps open and applying traction. A war wound in a comparatively young man, which necessitated a mid thigh amputation almost always had a virulent mixed infection plus a latent period before operative therapy could be carried out. Medical officers became so thoroughly indoctrinated with the principle of traction on stumps which were left open, that some of them have permitted this practice to become standard in amputations for peripheral vascular disease as well. Other surgeons maintain that civilian experience has taught them that results will be good when most mid thigh amputa-

tions for peripheral vascular disease are handled by tight or loose closure according to the clinical condition and the extent of blood vessel involvement which are ascertained during operation. They are convinced that most stumps heal satisfactorily and quickly and that when the other technique is used wounds take much longer to heal aseptically and nitrogen balance is difficult to maintain, and an end-bearing stump is produced which is far from satisfactory and frequently in need of revision. Unless there is obvious ascending infection or marked thrombosis of the femoral vessels in arteriosclerotic or diabetic gangrene it has been our practice to close stumps by the approximation of muscle fascia and skin. Should there be evidence of wound infection or breakdown appropriate measures are taken. Generally the results have been better with this program.

Supportive therapy This strives to overcome the hazards of anesthesia, operative trauma, blood loss, a negative fluid electrolyte, and nitrogen balance and the impaired function of vital organs. A good anesthesia with ample oxygenation, a continuous intravenous drip of whole blood, plasma, human serum albumin, or glucose in saline solution, and the use of analeptics such as synephrin in patients who are in a shock state, all contribute to a safer operative procedure. Old patients can take more than 500 cubic centimeters of blood or other fluid intravenously with far greater safety than is generally supposed, provided that the drip rate is regulated to serve the clinical condition of the patient, as the diminished elasticity of the vascular system with its concomitant lack of adaptability to rapid changes in blood volume may put an increased load on the already damaged heart and result in acute cardiac dilatation. Improved color, pulse, and blood pressure readings indicate the necessity for a slower infusion rate.

POSTOPERATIVE PROPHYLAXIS AGAINST MORTALITY

Supportive therapy This aims to correct shock induced by blood loss and trauma, and to restore impaired circulatory function and nutritional balance. The value of whole blood in the first two and its beneficial effect on the circulatory and kidney functions are established. There is no ideal substitute for oral food intake. When there are factors which vitiate comparatively normal assimilation or when tube feeding is difficult, parenteral alimentation serves its supporting and life saving purpose. Elman, Werner, Koop (21), Fingerstrom, and Mason and Zintel have discussed basic principles for the maintenance of nutrition in surgical patients with particular emphasis on nitrogen, fluid, and electrolyte balance. In view of the dis-

turbed cardiac and kidney functions in the aged the margin of safety for intravenous infusion is diminished and in selected cases it may become advisable to use clyses. Patients who have salt retention or in whom this is induced by too high salt administration become susceptible to water retention and fixation of extracellular protein. A urine with a specific gravity below 1.015 points to adequate hydration and it is desirable that the output should be at least 1,000 cubic centimeters. The average daily water requirement is 2 liters. This may have to be doubled in patients who have suffered dehydration through vomiting, diarrhea, intestinal fistulas, anorexia, excess perspiration, or gastrointestinal decompression. Mulholland *et al* (31), Brunschwig *et al*, and Casten *et al* have made studies to show that there is postoperative nitrogen loss. One gram of protein per kilogram of body weight is an average daily requirement, but after operative or other traumas such requirement may have to be doubled or tripled in order to maintain a positive nitrogen balance. Lowered physical activity can diminish nitrogen metabolism, but a high carbohydrate intake may compensate for this. Hydrolyzates and parenteral administration of pure amino acids furnish a high nitrogen intake. The rapidity with which the amino acids may be given may facilitate early ambulation and better sleep. It is advisable to provide glucose and salt apart from the amino acid mixture. The use of one-sixth molar sodium lactate solution to prevent acidosis is indicated. The parenteral maintenance of a nitrogen balance is continued until the daily food intake provides it.

Early ambulation It is generally conceded (23) that this radical departure from past practice with its tendency to prompt promotion of normal function has had a definite effect in the reduction of postoperative morbidity and mortality and has proved to be a conservative procedure. Over 30 years ago one of our teachers of surgery at the College of Physicians and Surgeons, Columbia University, the late William Cogswell Clarke, preached a surgical sermon of early in-bed mobilization of postoperative patients and he exhorted his students to let em kick their legs around. He feared the bad effects of a slowed circulation. Education of the public has dispelled the fear of early ambulation and contributed to confident co-operation. The method has cut in half postoperative pneumonia, distention, difficulty in urination, elevation of temperature, wound disruption, and thrombosis. Formation of bed sores has been diminished, atrophy of disuse lessened, vital capacity increased, and the cough reflex stimulated. Morale has been strengthened, appetite,

sleep, and strength improved, and the necessity for sedation diminished. Hospitalization and expense have been curtailed. It has been gratifying to note that, especially in geriatric patients, the earlier the ambulation, the better. For example, practically all of our patients have inguinal hernia repair under local anesthesia and they are encouraged to walk and use the bathroom on the day of operation. A patient who has an abdominoperineal resection sits in a chair the day after operation and takes a few steps. Early ambulation is interdicted in those who are in danger of imminent cardiac failure or who have hyperpyrexia, weakness, profound shock, or severe hemorrhage.

Oxygen therapy This is routine for at least 24 hours after operation for patients who have had the more major surgical procedures, especially those in the upper abdomen. Oxygenation in the aged, many of whom have some type of anemia or local or general anoxia, increases the oxyhemoglobin with the result that pulmonary and tissue respiration is better and easier, vital capacity is increased and the cardiac load is diminished. In order to obviate oxygen want, it is essential to relieve respiratory depression, obstruction in the respiratory system, shock, and oxygen replacement by other gases. A 50 to 100 per cent increase in concentration of alveolar oxygen is desirable. The administration of 100 per cent oxygen causes a 10 to 15 per cent increase in oxygen in the arterial blood and a slightly higher increase in the venous blood (6). This can reduce the mortality in shock (4, 17) acute cardiac decompensation, circulatory failure, pulmonary edema, pneumonia, and abdominal distention. When the use of an oxygen tent is impractical, oxygen insufflation may be substituted with the help of an oxygen mask, an oropharyngeal catheter or nasal cannulae.

Phlebothrombosis thrombophlebitis and embolism. The highest incidence of thrombosis is likely to occur in the older age groups (2) and during the colder months (16). The major etiologic factor is stases in the deep leg veins. In our autopsy findings unsuspected massive thrombosis occurred in 9 per cent of the patients. In 7 per cent, this was the principal cause of death. Thrombophlebitis with its evident symptoms and signs, is usually recognized early and easily provided that a careful, routine daily examination of the lower extremities is made. The thrombus of phlebothrombosis, however, is more insidious, and difficult to diagnose. The presence of compensatory dilatation of superficial veins, edema of the ankle, cyanosis of nail beds, calf tenderness, and Homan's sign suggest the presence of phlebothrombosis,

especially if the temperature, pulse, and respirations are mounting. Embolism may be easily overlooked, but if it is diagnosed it may be the first lead in the recognition of the basic pathological condition. In this connection, it is suggested that the descriptive adjective "bland" associated with the thrombus should be abandoned, for no thrombus can be bland in view of its potential embolic hazard.

Early ambulation in its strictest sense, has been the most potent prophylactic against thrombosis. The observations of Morton and his associates on thrombosis and embolism, based on autopsy findings, are significant. They emphasize, among many other things, the most common incidence in the sixth, seventh and eighth decades, and the tendency toward fatal embolism in patients with impaired cardiac action. The "jackknife" position in bed predisposes to puddling in vessels near the popliteal and femoral creases. These authors recommend slight elevation of the extremities in extension. Allen (1) is convinced that geriatric patients should have prophylactic interruption of both superficial femoral veins in order to guard against thrombosis and embolism. His conclusion is based on a well controlled group of 458 cases. He is averse to the use of anticoagulants in the aged if they have metabolic, renal or liver disturbance, arteriosclerosis, or hemorrhagic diathesis. We have not hesitated to use heparin and dicumarol in indicated cases of thrombosis, provided that there is a daily check on the prothrombin time. For the present we prefer this therapy together with early ambulation, to the use of prophylactic ligation of the superficial femoral vein. It is possible that this concept will change. Vein ligation above the clot, thrombectomy and the use of anticoagulants for phlebothrombosis, especially if complicated by embolism, is an accepted procedure. When femorofemoral thrombophlebitis is the presence of repeated infarcts is suspected, life-saving ligation of the common iliac vein or inferior vena cava may have to be performed (Neal et al.). Aycock and Hendrick have had remarkably good results in thrombophlebitis from paravertebral lumbar sympathetic block with 1 per cent procaine hydrochloride and monobromsaligenin.

Decubitus ulcers These, often multiple, are commonly seen in aged surgical patients, especially those who have neurological conditions. The most frequent sites are in the sacral, trochanteric, calcaneal and scapular regions. Our autopsy statistics show that decubitus ulcers were the contributory cause of death in 5 per cent of the patients. Like all open wounds, they frequently initiate a serious downhill clinical course by de-

pletion of protein reserve and at times, by sepsis. Their debilitating effect produces anorexia and diminished resistance to infection resulting in a vicious cycle of persistent chemical imbalance or sepsis unless appropriate therapy is vigorous. A significant contribution to such therapy was made by Mulholland *et al* (32) who demonstrated that decubitus ulcers will heal quickly if hypoproteinemia is reversed and a positive nitrogen balance is maintained. Additional therapy which has yielded the best clinical results is the relief of local pressure by early ambulation, repeated change of position in bed, rubber rings and air mattresses, the maceration of skin due to incontinence. Basic surgical principles in the local treatment of the ulcer are indicated.

We have tried without success plastic closure of some of the larger decubitus ulcers. The successful results which have been obtained by this procedure in young soldiers are difficult to duplicate in the aged because of circulatory and nutritional disturbance diminished resistance to infection and in some cases incontinence.

Pneumonia The high morbidity and mortality of postoperative pneumonia make this one of the major problems in geriatric surgery. This disease was the principal cause of death of almost one third of our patients. The stealthy clinical signs, the masked and sometimes absent physical signs, the unpredictable temperature curve and the common absence of cough all contribute to make it easy to overlook the diagnosis, especially if the patient has antibiotic therapy. The most reliable diagnostic aid is the chest roentgenogram. The most important signs are increase in pulse and respiratory temperature and scattered subcrapant rales. Good anesthesia, early ambulation, deep breathing, supportive cardiac therapy, and the routine postoperative use of penicillin and oxygen are the strongest prophylactic measures.

Fresh air and sunshine The influence of the physical and mental stimulation of fresh air and sun line with the associated change in scenery cannot be overemphasized. One of the characteristics of aged ward patients is an inertia which tends to make them congregate in groups in loaves even when weather conditions are favorable. They have an unfounded fear of drafts and pneumonia especially in the winter months. Recently on a mild and beautiful grand rounds day, most of the ambulatory male patients were found seated in the day room. One of the old men was told to take a lavage of the outdoors on a porch. He took a lavage and it left beaten but amused.

Attractive day room, mild recreation such as checkers and card games, reading and various forms of occupational therapy help create a resistance to the outdoors. It is part of the job of the nursing staff to overcome this resistance.

STIMULI

1. The operation and function of the surgeon make nutrition becoming more important. 2. The progressive increase in the span of life.

The principal and contributory causes of operative mortality are enumerated from an analysis of 100 consecutive autopsy protocols of extreme surgical risk patients over 60 years of age. The three outstanding principal causes of death were: 1. bronchopneumonia (8 per cent), 2. bilateral and pulmonary edema (per cent), 3. pulmonary thrombosis and embolism (per cent). The three outstanding causes of death were: 1. bronchopneumonia, 2. bilateral and pulmonary edema, 3. pulmonary thrombosis and embolism. The three outstanding causes of death were: 1. bronchopneumonia, 2. bilateral and pulmonary edema, 3. pulmonary thrombosis and embolism.

4. The importance of early operative intervention in the geriatric patient preparation and technique is emphasized. 5. It is to be expected that deaths from emergency operations will be at least two and one quarter times greater than deaths from non-emergency operations.

6. There are various measures which help in preoperative preparation against mortality. It is important to establish a reasonably correct diagnosis in order to plan a surgical procedure. Old people do not tolerate surgery well in hot or humid weather. The importance of a positive fluid electrolyte and fluid balance in the elderly is emphasized. The importance of a positive fluid balance in the elderly is emphasized. The importance of a positive fluid balance in the elderly is emphasized. The importance of a positive fluid balance in the elderly is emphasized. The importance of a positive fluid balance in the elderly is emphasized.

psychological approach to the patient and an optimistic bedside manner are very constructive. Many patients die because conservatism at the wrong time brings them to operation too late. This is true especially in conditions which involve infection, gangrene, malignancy and obstruction in various systems.

6. There are various measures which help in operative prophylaxis against mortality. Anesthesia for the aged is evaluated. Cyclopropane is the preferred general anesthetic. All general anesthetics are best when accompanied by ample oxygenation and at times by curare. Cryanal anesthesia for lower extremity amputations should be limited to those patients who are extremely bad risks or to those who have spreading infection.

Reasonable speed, gentle manipulation, and careful hemostasis are all part of a good technical procedure. The use of a Murphy button for palliative gastroenterostomy in carcinoma of the stomach is recommended. Except in obvious ascending infection in peripheral arteriosclerotic or diabetic vascular disease, it is preferable to close amputation stumps loosely or tightly according to the findings at the time of operation. The use of a tourniquet is interdicted because the blood vessels are vulnerable to thrombosis.

The use of supportive therapy by the parenteral administration of blood, blood substitutes, glucose, and saline solution has been life-saving.

7. There are various measures which help in postoperative prophylaxis against mortality. Supportive therapy for shock, the correction of impaired circulatory function and the maintenance of nitrogen, fluid, and electrolyte balance are presented. Early ambulation, oxygen therapy, the detection and therapy of phlebotrombosis, thrombophlebitis, embolism and pneumonia, and the prevention and therapy of decubitus ulcers, all contribute to lessen morbidity and mortality. The importance of good nursing, fresh air and sunshine is emphasized.

SURGERY OF THE HEAD AND NECK

HEAD

Classification of Extensive Cysts of the Jaw
Victor Boyko *J Oral Surg*
The present review discusses the classification of extensive cysts of the jaw in terms of their origin, histology, and clinical presentation. The author emphasizes the importance of a thorough histological examination in the diagnosis of these lesions. The review also discusses the various treatment options available for these cysts, including surgical resection, marsupialization, and medical management. The author concludes that a multidisciplinary approach involving histopathology, radiology, and surgery is essential for the optimal management of these complex lesions.

HEAD

Classification of Extensive Cysts of the Jaw
Victor Borso J Oral Surg., 1947 5 325
The present study centers about
genetic cysts

The present study centers chiefly around odontogenic cysts. Usually unilateral such cysts may reach extensive proportions and erode through the bone. Those in the maxilla may obliterate the antrum extend into the orbit the pterygoid fossa and invade other vital structures. The most common types are:

The most common type of cysts are the radicular cysts which extend from the periapical regions. These are usually detected during routine oral examinations and are therefore seldom products of marked tissue damage.

The second type or the follicular group of cysts results from retrograde changes during tooth development with subsequent enlargement of the enamel organ. The stage at which changes occur determines whether the follicular cyst is to be simple dentigerous periodontal, odontome, or multiple. When extensive follicular cysts particularly of the dentigerous type may contain potential ameloblastoma tissue.

The third group, the ameloblastoma or a laminar properties and necessitates wide excision. Traumatic or hemorrhagic cysts and cysts arising from embryonic fissures though not odontogenic may present similar findings and often lend themselves to the same form of treatment as the radicular and follicular types. In combination with the radicular and the injection of lipiodol into the cyst may be of aid in establishing a diagnosis. The diagnosis however may remain in doubt until aspiration or several tissue biopsies (or both) are performed. When essential teeth or roots are involved and are uninvolved, the

When essential teeth or vital tissue structures are uninvolved, the lesion is enucleated or the cystic membrane is excised, care being taken to avoid deformity and to maintain normal function by preserving as much of the alveolar ridge and muscles as is safe. In the presence of ameloblasts and lesions with malignant tendencies, radical resection often followed by radiation therapy, is urged. Exposed teeth may be retained, if urged after their development.

Exposure by radium therapy, is urged after their devitalization or they may be left temporarily to aid in the healing process. However when extensive cysts encroach on vital structures conservative operations may be substituted. The open or Parisch procedure consists in placing a window in the most accessible portion of the cyst thereby converting it into an accessory part of the oral cavity. Similarly communication may be established by means of a foreign body which permits drainage and allows irrigations to be carried out until the cyst shrinks and healing occurs. In some

in instances a portion of the lesion may be removed in a radical manner whereas the balance of the cyst may be treated more conservatively. Moreover, eradication becomes possible occasionally only after a preliminary conservative operation has been performed.

The affirmative of soft tissue edges the immediate appliances to retain bone fragments in a functional position in the institution of oral hygiene is of great importance with which to combat infection in postoperative exercises and physiotherapy are all helpful in achieving a successful result.

DAVID H. LANE M.D.

The Use of Vitallium Plates to Maintain Function following Resection of the Mandible
Wm Pl of Acoust Surg 1948 3 73
Resection of the mandible
Lippincott

Resection of the mandible necessitates immediate operative fixation of fragments to prevent external and internal rotation resulting in deformity. In a child feeding problem and severe deformity a fault with teeth retention of the proper relationship between fragments with the later restoration of bone continuity can be accomplished with intracutaneous wiring of the mandible. In edentulous adults immediate bony grafting in our experience has failed because of either al contamination or incomplete fixation of the fragments. Following resection of the mandible without internal wiring, depression of the mandible and depression of the maxilla are secondary to the immediate use of Vitallium plates fixing both fragments and speech in their original place and maintaining rigidity of the mandible during the period between operations have been success fully used to prevent these sequelae.

Simple Sherman type plates of vitallium in varying sizes can be bent to proper curvature in the operating room. If necessary a specially curved plate can be prepared in any dental laboratory equipped to make vitallium prostheses. The area to be resected is outlined the metal plate is bent to the approximate desired curvature with a pair of pliers or the fingers, the positions of the plate holes are marked with drill holes made into the bony part to be left. After the oral cavity has been closed tightly the wound irrigated and the instruments and gloves changed the plate is attached by small vitallium screws or bolts.

plates can be allowed to remain in position for a considerable period of time in order to stabilize the bone fragments and prepare them for a later graft.

LOUIS T. BRANT

EYE

The Problem of Sympathetic Ophthalmia. BEN MARD SAMUELS. *Irish J. M. Sc.*, 1947, 26:1-610.

The problem of sympathetic ophthalmia is discussed. The author points out that the disease is characterized by the appearance of a specific infiltration in the pigmented and highly vascular uvea. This infiltration is composed of three elements: lymphocytes, epithelioid cells, and giant cells. Artificially made openings of the eyeball with incarceration of uveal tissue generally result in sympathetic ophthalmia.

Wounds of the sclera in the danger zone, i.e. over the ciliary body, are more serious than wounds elsewhere because of the greater tendency of the uvea to prolapse. Ruptures at the limbus are most grave because the root of the iris, alone or together with the ciliary processes, may become incarcerated. The larger the perforation the greater the hazard.

Enucleation, iridectomy, and repair of iridodialysis are unsafe procedures. Cataract extraction with a flap incision is considered much safer than linear extraction. Sympathetic ophthalmia may follow operations for glaucoma regardless of the size of the opening but not operations for detachment of the retina. Generally speaking, as long as an eye remains hard after an operation the probability of sympathetic ophthalmia is remote. Cataract extraction and operations for glaucoma are the two most common surgical procedures which result in sympathetic ophthalmia.

From 2 to 13 per cent of all cases of sympathetic ophthalmia originate in eyeballs with post-traumatic endophthalmitis septica.

The incidence of sympathetic ophthalmia after septic panophthalmitis is about 3 per cent.

The presence of an intraocular foreign body makes the eye sensitive and may excite irritation of the other eye.

Clinically sympathetic irritation precedes the pathologic signs of sympathetic inflammation. Irritation is a warning of impending sympathetic ophthalmia. It disappears within a few days after the enucleation of the injured eye. Actual inflammation begins in the uninjured eye with disturbance of vision, pain, fine grayish precipitates on the posterior surface of the cornea, adhesions, vitreous opacities, and characteristic sharply defined small yellowish patches in the choroid.

In genuine sympathetic iritis (iritis maligna) the entire posterior surface of the iris is agglutinated to the capsule of the lens, unlike iritis serena in which the pupil is free or plastic iritis in which incomplete adhesions are confined to the pupillary zone. The presence of grayish nodules at the pupillary border and on the lens capsule is considered the most significant clinical sign of sympathetic ophthalmia in the anterior chamber.

Various theories have been presented to explain the pathogenesis of sympathetic ophthalmia—allergy and infection (tuberculosis or virus infection).

The time to enucleate the injured eye is (1) when the fellow eye is irritable, even if it be apparently normal (2) when keratic precipitates appear in the fellow eye (3) in cases in which there is no hope that the eye will ever again be serviceable and (4) when endophthalmitis is present.

The eye should not be enucleated (1) when the wound heals properly the tension is good, sight is retained, and the fellow eye shows no irritation (2) when the injured eye still has some vision after the fellow eye has become severely inflamed (3) when both eyes are violently inflamed and (4) when panophthalmitis is present. Enucleation should be postponed until the inflammation has subsided.

Iridectomy for relief of secondary glaucoma should be avoided. Paracentesis is the sole operation that is permissible.

A complicated cataract which develops in the sympathizing eye should not be removed for many months.

With regard to medical treatment, it is pointed out that miotics may increase the central synchia, and mydriatics may produce glaucoma. Salicylates, mercury salvarsan, tuberculin sulfonamides, penicillin and fever therapy have been tried.

JOSEPH ZUCKERMAN, M.D.

On Results Obtained by Total Conjunctival Hooding of the Cornea for Serpiginous Ulcer. A. KATZENTZ. *Bril. J. Ophth.*, 1948, 32, 36.

The author reports 56 cases of serpiginous ulcer treated by total hooding as compared to 119 cases in which the ulcers were medically treated, on the basis of visual acuity and hospitalization time.

The procedure is as follows. The bulbar conjunctiva was detached all around the limbus and was undermined into the upper fornix. The ulcerated parts of the cornea were scraped and the conjunctiva was anchored with catgut sutures in the episcleral tissue in a horizontal line 3 mm. below the cornea. Pain, lacrimation, irritation, and edema disappeared shortly after hooding. Removal of the hood was done not less than 6 months after the operation in order to prevent recurrence of the ulcer. Total hooding without prior medical treatment was recommended when vision was limited to hand movements or less, since it guarded against full visual loss. The number of improved cases and the improvement of vision were almost twice as great with the hooded method as compared to the medical treatment. Hospitalization time was cut nearly in half. This method has been extended by the author to all unhealed or poorly healing acute and chronic keratic processes, with good results.

ROBERT H. JOHNSON, M.D.

Human Conjunctiva Grafted on the Chorioallantois of Chick Embryos. A. FRIEDENBERG and W. KORNBLUTH. *Arch. Ophth.*, Chic., 1948, 39: 67.

The authors report the grafting of human conjunctiva on the chorioallantois of chick embryos. An oval piece of conjunctiva was removed from the

lower fornix of the human being and transferred to an isotonic solution of sodium chloride containing penicillin. Fertile hens eggs incubated for a period of 8 to 12 days were used in the grafting experiments. After cleaning the egg with alcohol a one centimeter square window was cut in the shell. The shell was then perforated at the location of the air bubble with a sterile needle and the air aspirated. In this way the fibrous membrane was separated from the adherent chorioallantoic membrane of the shell which made it possible to cut the fibrous membrane without injuring the chorioallantois. A 2 mm. to 3 mm. square piece of conjunctiva was deposited on the chorioallantois at the site of the large membrane vessels. The shell window was framed with paraffin and sealed with a cover glass. The needle hole was sealed and the egg was then incubated at 38 degrees centigrade. Twenty four hours later 300 units of penicillin were instilled on the chorioallantoic membrane near the graft. This was repeated 48 hours later. After a period of 6 days the experiments were concluded and the graft together with the adherent chorioallantoic membrane was removed and then stained.

At the end of the 6 day period of incubation the conjunctival graft was pinkish in color and was adherent to the chorioallantoic membrane. The vessels of which were widened and more numerous. Microscopic examination showed that the epithelial cover of the transplanted conjunctiva varied in thickness but was usually thinner than normal. The cellular architecture was usually altered. The arrangement in layers was not always clearly discernible and the regular position of the nuclei was disturbed. The individual epithelial cells fairly constantly presented a normal appearance and were usually well demarcated. There was no distinct division between the epithelium and the subepithelial tissue. Groups of epithelial cells seemed to penetrate deeply into the subepithelial tissue at the border. Frequently the epithelial cover was infiltrated with chick polymorphonuclear leucocytes. Mitotic figures were noted in all layers of the conjunctival epithelium.

The subepithelial tissue was usually well preserved. The number of mononuclear cells was not increased and the stroma contained a dense meshwork of collagen fibers. In many grafts a scanty infiltration of polymorphonuclear leucocytes was observed. The cells accumulating mainly at the border between the epithelium and the subepithelial tissue. Occasionally small sharply delimited necrotic areas were encountered within the subepithelial tissue. The grafts showed an abundance of wide capillaries which arose from the chorioallantois and penetrated the graft. The capillaries were lined with flat and cuboidal cells and engorged with nucleated chick red blood cells. Occasionally human red blood cells were seen. The chorioallantoic membrane lost its ectodermal cover where the graft became adherent but the ectoderm and the conjunctiva each maintained their own character. Only rarely were necrotic areas seen in the chorioallantoic membrane.

These experiments showed that it is possible to maintain fairly healthy human conjunctiva outside of the body without substantial alteration. Survival of the transplant is due to the fact that the graft is quickly incorporated into the vascular system of the chorioallantois. The vascular system of the conjunctiva probably becomes connected with that of the chick embryo. The pathological feature noted most frequently in the conjunctival graft was the infiltration of the polymorphonuclear leucocytes which originate in the chick embryo. This is probably a response of the host to a foreign tissue and apparently does not interfere with the survival of the graft. Two reasons for unsuccessful grafts were infection and a tendency of some grafts to sink into the mesoderm. ROGER H. JON 30: 1 M D

Transplantation of Vitreous. A Preliminary Report HERBERT M. KATZ and JOHN BLUM. *Brit J Ophth* 1947 31: 360.

The authors conclude from their experiments on rabbit that transplantation of vitreous material leads to complications. At a later date they expect to amplify this report by experiments with human material. Several methods of transfer of vitreous were employed in 39 eyes.

Transplantation of vitreous was complicated by retinal detachment and cataract formation. Detachments of the retina in rabbits usually heal spontaneously, however a few did not heal. Cataracts resulted from injury during the operation. There were no cases of chronic nevitis.

Transplantation of the vitreous was found to be more successful than replacement with saline solution because the eye metabolizes the injected vitreous and accepts it into its own structure.

Of 39 rabbits eyes followed up for a period of 6 months, 6 developed detachment of the retina, 2 developed traumatic cataracts and 7 presented a localized fibrous tissue proliferation around the puncture site.

These possible complications should be borne in mind when transfer of vitreous is considered as a clinical procedure. JOSEPH ZUCKERMAN M D

Peripheral and Central Disturbances of the Visual Fields. An Aspect of Ophthalmology. N. A. STREITWASSER. *Brit J Ophth* 1947 31: 21.

The author discusses some peculiar disturbances of the peripheral and central fields of vision. He presents 3 cases which he believes represent a form of disturbance of the peripheral vision or of central vision or both which does not have an organic or functional basis but is a disturbance of kinetic factors as revealed by the study of the light and its correlate convergence. He states that this condition is not yet recognized in ophthalmology as a clinical entity. He is of the opinion that kinetic treatment which affects adduction abduction and lateral fusion can effectively cure limitation of the peripheral field and failure of the central field of vision. JOSEPH ZUCKERMAN M D

A Case of Metastatic Osteosarcoma in the Choroid.

V T LUNA. *Bull J Ophth.*, 947 3 773.

Metastasis to the eye is extremely rare. The author reports a case of osteosarcoma of the choroid which metastasized from a primary growth in the chest. Metastasis was presumed to have extended from an erosion in the carotid artery. The condition began with a sarcoma of the knee following injury. After amputation metastases appeared in the chest. When the eye was first examined a patch of scleral hyperemia was present in the lower nasal area, the anterior chamber was shallow, the pupil was dilated and did not react to direct light, but did react consensually. The tumor was examined biomicroscopically. There were two nodules one extending from the disc to the equator and the other from the equator forward. There was no visible pigmentation. The solid nature of the nodules was demonstrated by transillumination.

Later the detachment became total so that the tumor was no longer visible. Postmortem examination of sections of the eye revealed osteosarcoma which formed irregular trabeculae of osteoid tissue. The centers of a few trabeculae presented calcifications, but the bulk of the tissue was noncalcified. The tumor was a sarcoma which originated from bone.

The bone sarcoma in the knee had evidently spread to the mediastinum and from there to the eye by vessel erosion. The presence of a double tumor in the eye was suggestive of its metastatic origin. The sections showed the distinctive cell pattern of bone sarcoma.

Cases have been reported previously in which metastases occurred in the second and third nerves in the cranium, and in the second nerve and in the muscles within the orbit. Both eyes were affected by deposits in the choroid.

A similar case was described by Weiner (1903) and by Ballantyne (1905) following primary sarcoma of the chest. In both cases metastases occurred in the suprarenal gland, and in the brain with deposits in the optic nerve extending from the disc to the retina. Heine (1890) described a metastatic sarcoma of the optic papilla. Schless Gemmuse and Rogh (1879) described a pigmented tumor of the disc which extended from a malignant melanoma of the skin. Neese (1907) reported a choroidal tumor which metastasized from a sarcoma of the breast and Elschnig (1926) reported a tumor of the iris originating from a primary lesion of the ovary.

JOSEPH ZUCKERMAN M D

Intramural Vascular System (Vasa Vasorum?) In Retinal Vessels. ARNOLD LOWENSTEIN. *Arch. Ophth.*, Chic., 948, 30 9.

Vessels within the wall of retinal vessels have not hitherto been recognized. In general, only the walls of vessels with a caliber greater than one millimeter are provided with vasa vasorum which arise from adjacent small arteries and form a dense capillary network in the adventitia. It has been shown that an intramural vascular system exists in the sclerosed

aorta and in sclerosed coronary vessels. Here a rich vascular system has been found in the intima and within and around the arteriosclerotic plaques. In arteriosclerotic coronary arteries, intramural vessels arise from the lumen of the partly occluded vessel. A similar system was also found in the veins. This is not found in healthy vascular walls in young people. The author has observed single capillaries running within the hyaline thickened wall of sclerosed retinal vessels. The walls are extremely thin and difficult to see. The majority of intramural vessels run parallel to the lumen though they also run obliquely and in a circular course. They are more frequently found at points of bifurcation and, on serial sections, are seen to open into the lumen. Frequently the site of origin of intramural vessels in the intima was surrounded by a group of endothelial nuclei. The author was able to follow the intramural vessels, which are predominately capillaries, from their lumens in the retinal vessels into the hyaline coat and to demonstrate union with sister branches and the adjacent retinal vessels. This condition is never observed in normal retinal twigs. He found newly formed intramural vessels both in hyalinated arteriosclerotic vessels and in a case of subendothelial fatty necrosis, a typical atheroma. A large number of intramural capillaries were found in a patient with thrombosis of the central retinal vein. In vasculitis retinal, some regular capillaries were conspicuous and sharply delineated. In other places a far more irregular system of capillary channels had replaced the main vessel. These vessels contained a multitude of endothelium-lined lumens separated by a nu- cleated granular substance.

The intramural vessels, for the greater part of their course, remain within the hyalinated wall whether they run parallel to the lumen, in circles, or in spirals. They serve the nutrition of the diseased tissue. The metabolism of the normal wall of the small retinal vessels is maintained by the blood stream in the lumen, the diseased vessel wall, the hyaline thickened coat especially demands more nutrition. The changed consistency of the tissue may act as an impediment to the movement of fluid. It is likely that oxygen tension and lack of nutrition are responsible for the stimulation of the formation of additional blood vessels. Since these intramural capillaries are made up of a simple endothelial layer and since they connect directly with the lumen of the vessel their intracapillary pressure is higher and they rupture more easily. The intramural vessels may serve to transport blood over an occluded or narrow part of the lumen.

ROGER H. JOHNSON M D

The Blood Supply of the Optic Nerve. DERRICK VAIL. *Am. J. Ophth.*, 948 3 1.

The purpose of this paper is to review the anatomy of the optic nerve and its blood supply and to consider a few lesions in this regard. The gross anatomy of the optic nerve and chiasm are considered and their relationship to the surrounding structures

within the brain and throughout the course of the optic nerve are discussed in detail. The chiasmal portion of the basal cistern which continues along the optic nerve toward the globe is reviewed.

The author believes that there is a separation between the interganglionic space and the perivascular connective tissue of the central vessels where they enter the optic nerve. The blood to the intracranial portion of the optic nerve is supplied chiefly by minute branches from the internal carotid artery and sometimes by the ophthalmic artery below and superiorly by the anterior cerebral and anterior communicating arteries. The intracranial portion is supplied by pial vessels arising from the internal carotid and anastomoses with septal vessels from the orbital and intracranial portions of the nerve. The orbital portion is supplied by vessels that pierce the dura behind the entrance of the central vessels and those that join the pial network anteriorly at the site of the entry of the central vessels. The upper and lateral portion of the periphery of the nerve is supplied by branches of the ophthalmic artery the posterior ciliary arteries and recurrent or collateral branches from the central artery. The central portion of the nerve is supplied by branches from the central collateral artery and occasionally by a posterior axial branch from the central artery. The central artery usually comes from the ophthalmic, the long internal ciliary the external ciliary or the short posterior ciliary arteries. Where it enters the dura it gives off branches which go backward and forward and join the pial network to send branches to the optic nerve. Other branches from this network are sent to the lamina cribrosa and backward through the center of the optic nerve. The central retinal vein has numerous anastomoses near the papilla. After it leaves the nerve it becomes the venous network in the orbital fat and empties into the cavernous sinus, the superior orbital vein the inferior ophthalmic vein or several combinations. The posterior central vein of the optic nerve collects blood from the orbital portion of the nerve and empties into the cavernous sinus.

The author correlates various details of the anatomy with clinical pictures that could be based on anatomical changes. ROGER H. JOHNSON M.D.

EAR

Escape of Cerebrospinal Fluid Into the Wounds of Operations on the Temporal Bone H. I. LILLIE and ARTHUR A. SPAR. *Arch. Otolaryng. Chik.* 1947 46 779.

An injury to the dura which permits the escape of cerebrospinal fluid into the wound during the course of an operation on the mastoid might seem alarming because of the serious implications of impending meningitis. However the experiences reported seem to indicate that the difficulties may be overcome by surgical methods.

A review of the available literature pertaining to postoperative cerebrospinal otorrhea is given. The

factors involved in the origin of a cerebrospinal fistula are described and means of preventing the formation of a permanent cerebrospinal fistula are discussed. Methods which have been found successful in 4 cases for repair of dural defects of various sizes are described.

It would appear obvious that should an injury to the dura, which permits the escape of cerebrospinal fluid occur during an operation on the mastoid process it should be closed immediately rather than at a subsequent operation.

In case the escape of cerebrospinal fluid occurs as the result of the dislocation of the stapes, the precedent established is that any surgical interference be deferred because the escape of the fluid is usually controlled by natural reparative processes.

While it actually seems that when cerebrospinal fluid escapes into the mastoid wound the wound apparently clears of evidence of infection rapidly such a phenomenon should not be relied on to take place.

The present-day prophylactic use of penicillin and chemotherapeutic drugs is extremely beneficial and results are reassuring. These drugs are administered preoperatively and postoperatively. They were not available for use except in recently encountered cases.

NOSE AND SINUSES

Diseases of the Maxillary Sinuses Resulting from Pathologic Changes. KURT H. THOMA. *J. Oral Surg.* 1947 5 271.

The maxillary sinus can become involved by a large variety of pathologic entities derived from the teeth or from diseases of the maxillary bones.

Hematomas from rupture of the infraorbital and superior alveolar arteries as a result of fractures may continue to bleed as evidenced by pulsating pressure and repeated epistaxis. Surgery may be required. Infection of course adds to the gravity of the situation.

Odontogenic maxillary sinusitis usually results from periapical infection often in conjunction with excessive trauma incident to exodontia or other surgical procedures. When the process is acute the antrum may be entirely obliterated by the edematous and infiltrated lining and the presence of a mucoid or purulent exudate. Inadequate drainage leads to constitutional as well as local manifestations. The diagnosis is apparent from careful physical examination alone as a rule. Chronic infections however are more insidious in onset and the findings are frequently circumscribed initially. Later localized abscesses cysts or polyps or both may supervene and involve the antrum generally. Transillumination and roentgenography often aid in determining the cause as well as the extent of the infection.

Odontogenic cysts of the maxillary sinus are either radicular or less commonly dentigerous. Globulomaxillary cysts from the embryonic fissure between the lateral incisor and cuspid may similarly en-

that the foramen lacerum and the eustachian tube allow an easy gateway to the region of the petrous tip probably accounts for the high incidence of involvement of the fifth nerve and the nerves to the extraocular muscles. The cervical sympathetic supply to the eye may be interrupted either here or in the neck by cervical metastases. Pressure on nerves with resulting irritation and ablation phenomena easily explains all of the symptoms noted in the appropriate distribution of the involved cranial nerves. In one instance actual invasion of the temporal lobe took place with a resulting aphasia.

MOUTH

Dominant Inheritance of Cleft Lip and Palate in Five Generations. AVERY R. TERT and HAROLD F. FALLS. *J. Oral Surg.*, 1947 5 292.

The authors study concerns a pedigree of cheilognathouranoschisis complex extending back for five generations. The complex as a whole was found to demonstrate the typical pattern of dominant mendelian inheritance. The degree of dominance varied greatly among affected persons as did the expressions of the various aspects of the complex. The gene, however, exhibited sufficient dominance to fulfill the requisites of dominant inheritance of an irregular type. There was no evidence of sex linkage, sex limitation or sex influence nor was there any evidence in favor of the often expressed idea of greater frequency among males.

A marked variation in degree of expression of the gene was present. Singly or in combination these anomalies indicate that the affected person no matter how mildly involved is capable of transmitting the trait in either severe or mild form to approximately half of his or her offspring. The authors, therefore, believe that the severity of the trait in a parent is no indication of the severity which may be expected in the offspring.

This phenomenon of variable expression of a gene especially prevalent in the syndrome under discussion, is rather common in human heredity and unless all living members of a family are carefully examined for aborted forms of the complex in question, the typical mendelian inheritance pattern may not be apparent.

Attention was also called to the fact that the very rare human anomaly of accessory salivary glands of the lower lip may be an expression of the cheilognathouranoschisis complex. This association was described by Straith and Patton in 1943. The authors also clearly show that this defect imposes socioeconomic handicaps which depend upon the severity of the disfigurement. DAVID H. LYNN, M.D.

Palliative Procedures in Advanced Cancer of the Mouth. GRANT BICKSTAND. *Radiology* 1948, 50 10.

Under the designation of cancer of the mouth are included those malignant neoplasms occurring on the

vermillion portion (mucosa) of the lips, the buccal mucosa, gingivae, tongue (except for the base), the floor of the mouth, hard and soft palates, and anterior tonsillar pillars. Cancers of the tonsil, pharynx, and base of the tongue (all pharyngeal structures) will also be considered because of the continuity of structures with the buccal cavity and the similar problems which arise in the management of growth at these sites. Advanced cancers of the mouth and pharynx may be limited to a single anatomical structure or may involve several adjacent or distant parts of the body. Cancer of the lip may be advanced locally but still remain limited to the primary site or again it may extend to the corners of the mouth, the buccal mucosa, the gingival-buccal gutter or lower jaw and yet not metastasize to the neck. Since the majority of lesions involve the muscularis of the lip, such neoplasms will eventually reach the neck nodes by way of the abundant lymphatic channels of that structure. Advanced cancers of the buccal mucosa may also extend to the upper or lower jaw and will frequently show cervical metastases.

With cancer of the gums there may be considerable destruction of the jaw bone, either from the disease itself or from radionecrosis if portions of bone have been exposed to vigorous radiation therapy. The buccal mucosa, floor of the mouth, tongue, anterior tonsillar pillars, and lymph nodes of the neck may be involved either by direct extension or by way of the lymph vessels. Cancer of the tongue, while usually arising from the margins or base, may involve a large portion of that organ, the floor of the mouth, the tonsillar pillars, and the pharyngeal wall in most instances. In the advanced stage it will also show neck node metastases. Advanced cancers of the soft palate and tonsils of epithelial or lymphoepithelial origin are of a higher degree of malignancy than most cancers of the mouth and, therefore, besides direct extension to neighboring tissues such as the tonsillar pillars, floor of the mouth, base of the tongue, pharyngeal wall and extrinsic larynx, they almost invariably show neck metastases.

Most advanced intraoral cancers thus involve besides the site of origin, the adjacent structures or the lymph nodes of the neck or both. Therapeutically both the primary focus and the secondary nodes must be considered carefully from a surgical and radiological point of view to obtain the highest rate of cure and the greatest degree of palliation.

The most common symptom is pain which may have been present for weeks or months depending on the location and extent of the primary disease, the amount of infection present, and the degree of the metastatic involvement of the cervical lymph nodes. In cancer of the lip and of the anterior two-thirds of the mouth and in most adenocarcinomas pain usually appears late. It is limited first to the regional area, then extends along the lower jawbone, and eventually to the ear, neck, and side of the head, unilateral in the beginning but finally bilateral as the whole lip, the jawbone, and neck nodes are involved. In squamous cell carcinomas of the posterior third of

the mouth and pharynx, pain in the ear due to ulceration and infection is the early complaint. Later the pain increases in severity and is constant along the jaw and side of the head, involving both sides when the cancer has crossed the midline. Neck and shoulder pain appear as the metastatic nodes become large and fixed.

Tumor occurs due to ulceration and infection in the mouth or throat or cellulitis in the neck and mandibulo-temporal region. Lumps in the mouth or throat are often the first manifestations of adenocarcinomas and mixed tumors usually they are found in the buccal mucosa, soft palate or tonsillar regions. Growing slowly the tumor may attain large dimensions and may form a mechanical barrier to swallowing and talking before ulceration and infection occur.

Severe dysphagia with extreme loss of weight and strength is common with ulcerations of the mouth and throat and may extend to the hypopharynx or extrinsic larynx, and even to the esophageal opening. When the arytenoids and aryepiglottic folds become edematous, either from the disease or from secondary infection or radionecrosis, dyspnea and stridor may become evident. Bad taste and foul breath are associated with necrotic lesion. Bleeding from infected deep ulcers may terminate in anemia from long continued oozing or massive hemorrhage.

Lumps in the neck are often the earliest symptom especially in cancers of the posterior third of the mouth, tonsil and pharynx. They are painless at first but later become enlarged and fixed with pain and stiffness of the neck and shoulder in many cases ulceration, continuous between the mouth and neck occurs. Half of the face becomes a large oozing, drooling, bleeding, granular necrotic, foul-smelling ulcerated mass and the terminal course is protracted, painful and pathetic.

A biopsy from the margin of the growth or an aspiration of the palpable nodes may be done without fear of crossing the normal neck barriers or of complicating the case should a radical neck dissection be decided upon. A pre-biopsy should be avoided.

The majority of advanced cancers of the mouth are incurable. Highly malignant cancers of the posterior third of the mouth and pharynx are not readily amenable to surgery but fortunately they are radio-sensitive and fractional radiation gives fair results. Neck metastases are likely to be early and wide spread or even bilateral and respond more favorably to irradiation. Most bulky cancers of the lip with or without neck metastases are difficult to control by radiation therapy. Good results have followed wide excision of the primary lesion with plastic repair combined with radical neck dissection when the cervical nodes are involved. Radical resection of the lip, jaw, tongue, floor of the mouth or buccal mucosa with radical neck dissection is curative in many cancers which previously were regarded as inevitably fatal. The majority of these tumors grow slowly, metastases are often limited to the upper half of the neck and are not amenable to radiation therapy.

Fixation of the mandible is no longer considered a sign of incurability. For adenocarcinomas and mixed tumors surgical removal is the procedure of choice, both for the primary growth and the nodes in the neck.

In patients with highly malignant cancers of the posterior third of the mouth and pharynx, in whom an attempt at cure is justifiable, daily doses of 200 to 300 roentgens (in air) for a total of 4,000 to 6,000 roentgens per portal should be used. Smaller doses at longer intervals are used only as a palliative measure. For metastases to the neck nodes, roentgen therapy is the treatment of choice. Too large portals extending beyond the margins of the tumor are ineffective. Roentgen therapy in moderate doses is frequently of value in cleaning up infection and may make surgical intervention safer in many primary lesions. It may also be of value in certain cases of neck metastases preliminary to neck dissection. Gold seeds of radium implanted in the nodes combined with surgical removal or irradiation of the primary cancer, may be the procedure of choice for the aged and the weak. Recurrent cancers after surgical intervention call for palliative small doses of roentgen rays.

The palliative care of the patient with advanced cancer of the mouth is the obligation of the surgeon in those cases in which surgery is the treatment of choice. The task of the radiologist is not complete with the administration of roentgen rays and radium, but includes repeated examination, daily removal of slough, frequent packing of ulcers, institution of a proper dietary regime, relief of radiation reactions, and whatever contributes to the control of infection and the alleviation of the patient's suffering.

Effects of Vitamin A Deficiency on Thyroid Function Studied with Radioactive Iodine. MORMON, B. LARSEN and RICHARD J. W. ALLEN. *Endocrinology* 9:47-4, 1944.

Prompted by the lack of agreement concerning the effects of vitamin A deficiency on the thyroid function, the authors conducted an investigation of thyroid function in severe avitaminosis; radioactive iodine was used as a tracer.

The parents of the animals used in the experiment were maintained for a period of at least a month previous to breeding and for 14 days after birth on Sherman diet B without added lettuce or meat. On the fourteenth day mothers and litters were placed on a vitamin A-low diet. At 21 days the animals were divided into three groups: one with a deficient diet, one control group injected with 8 international units of vitamin A daily, and the third group with 20 mgm. of carotene per kilogram daily. The animals were injected intraperitoneally with a tracer dose of about 50 microcuries of I^{131} . The separation of iodine fractions was after the method of Perlman, Morton and Chalkoff. For determinations of total iodine, diiodotyrosine, iodine and thyroxine iodine

aliquots were digested and distilled according to the procedure of Taurog and Chalkoff

The experiment indicated that in avitaminosis A there is a decreased rate of formation of thyroxine. The glands of the rat were relatively heavier in the A-deficient group. The histological picture of A avitaminosis appeared as degenerative changes and distended thyroid follicles both present concomitantly. The total I^{131} uptake was not changed the inorganic I^{131} in the thyroid reached higher than normal values and decreased more slowly than in the controls

W FOSTER MONTGOMERY M D

Treatment of Graves Disease with Radioactive Iodine. MATO H. SOLEY and EARL R. MILLER. *Med Clin N America* 1948 32 3.

Radioactive iodine was first used in the treatment of thyrotoxicosis by Hertz in 1941. Hamilton Soley and Eichorn, Hertz and Roberts, and Chapman and Evans have done much of the fundamental work with this agent.

The authors injected 300 microcuries of carrier free radioiodine, I^{131} subcutaneously in rabbits and dogs. They found extensive necrosis hemorrhage polymorphonuclear infiltration and arterial changes in the thyroid at 10 days. After this time the fibrosis gradually increased.

A careful description of the technique of standardization and calibration method of administration measurement of activity and method of handling I^{131} is given. The uptake of iodine in normals is usually much less than 30 per cent. In frank untreated Graves disease it is usually between 40 and 80 per cent; therefore the use of tracer doses (100 to 250 microcuries) is of diagnostic value. In the dose range the number of iodine molecules is so small that no effect due to iodine is expected.

Thirty three patients with Graves disease were treated by orally administered radioiodine (I^{131}) and have been followed for a period of 3 months to 2 years. No nodular goiters were included since it is believed that these should be treated surgically. The smallest dose of I^{131} which produced a satisfactory remission was 800 microcuries the largest dose 9,150 microcuries. The authors recommend a schedule including an initial dose of 2,000 microcuries with repetition of similar doses at monthly intervals until the required total dose is given.

Twenty five of the patients in the series (75%) had satisfactory remission of symptoms and signs of hyperthyroidism in 1 1/4 to 7 3/4 months following the beginning of therapy. The average time was from 3 to 7 months. The results in the remaining 8 patients have been classed as unsatisfactory. These patients have either taken too long to return to normal or have not returned to normal within a year after treatment was started.

Careful studies were made of the change in estimated thyroid weight, basal metabolic rate, protein bound iodine, uptake of I^{131} in the thyroid and estimated time from the initial dose of I^{131} to return to normal

In the successfully treated patients the weight of the thyroids decreased from an average of 30 gm to less than 15 gm the basal metabolic rate dropped from an average of plus 30 to minus 10. The protein bound iodine dropped from an average of 10.6 to 5.7 micrograms per 100 cubic centimeters. The average total dose of I^{131} was 2,726 microcuries.

In the unsuccessful group the goiters were larger the basal metabolic rates higher and the protein bound iodine was higher. It is believed these sicker patients were not given adequate doses. They probably needed from 10 to 12 millicuries.

Within from 24 to 72 hours after the administration of I^{131} the thyroid becomes tender, the sedimentation rate is increased and the protein bound iodines are increased. The symptoms of hyperthyroidism from the fourth to the tenth day seem to be increased. Changes in exophthalmos after I^{131} therapy were not significant.

I^{131} has a half life of 8 days and 1 microcurie distributed through 1 gm of tissue gives 142 equivalent roentgens of beta ray energy during the course of its complete decay. Other clinics are using much larger doses than those used by the authors. As yet no one knows whether a single dose of 12 millicuries is more effective than 6 doses of 2 millicuries.

Studies of dosage problems, measurement of radioiodine and distribution of iodine in the thyroid indicate that further experience is necessary before conclusions can be drawn as to the place of this type of therapy in Graves disease.

ROBERT R. BIOLOW M D

Experimental Chronic Thyrotoxicosis in Guinea Pigs. The Hematopoietic System Liver Spleen and Endocrine Glands (La thyrotoxicose expérimentale chronique du cobaye. Le système hématopoïétique, le foie, la rate et les glandes endocrines) F. LAYANI, A. ASCHKENASY and J. MIRONOT. *Ann endocr* Par 1947 8 205

The authors reproduced hyperthyroidism in immature female guinea pigs by the administration of powdered thyroid and made the following observations:

1 Chronic thyrotoxicosis is accompanied by an increase in leucocytes polymorphonuclear cells, and eosinophils. The bone marrow becomes hyperplastic but the hemoglobin does not vary. This myelotropic action of the thyroid differs from that of the liver or hepatic extracts which are both cytopoietic and hemogloinopoietic.

2 There is a functional inhibition of the thyroid gland characterized by a loss of small acini, an increase in the amount and age of the colloid and a flattening of the acinar epithelium.

3 A hyperplasia of the adrenal cortex is found to occur.

4 There is a moderate hypertrophy of the spleen with reticular reaction but without lymphoid hyperplasia.

5 There are no histologic alterations of the liver

EDWARD W. GIBBS M D

Experimental Chronic Thyrotoxicosis in Guinea Pigs. The Osseous System (La thyrotoxicose expérimentale chronique du cobaye. Le système osseux) F. LAYAT, J. MIGNOT, M. CHAFFARD and A. ANCHUTSKY. *A. N. Endocr. Par.* 1947 8: 37

Prolonged intravenous administration of weak doses of powdered thyroid to guinea pigs produced certain bony changes. Radiologically there was a rarefaction of the femurs with a disturbance of the arrangement of the bony lamellae at the borders of the femoral head and trochanters. Histologically there was a diminution of phosphorus and calcium around the edge of the bone, a disappearance of the spongy diaphysis and a thickening of the cortex. No osteoclastic activity was observed.

The bone marrow showed evidence of hyperactivity which is in accordance with the hematopoietic activity of the thyroid. There was no consistent change in the serum calcium, phosphorus, or phosphatase. No findings were similar to those of parathyroid osteosis. EDWARD W. GIBBS, M.D.

The Mortality of Thyroidectomy (Mortalität der Strumektomie) M. RICHARD. *Meded. chir. acta*, 1947 4: 366.

The author reports a mortality of 0.34 per cent in 3,319 thyroidectomies (13 deaths) from 1931 to 1947.

The series includes all operations on the thyroid gland for nontoxic, toxic Basedow's, malignant, inflammatory and recurrent goiters. The 13 fatal cases were classified as nontoxic goiters (6), toxic goiters (6) and Basedow's disease (1). There were no fatalities in the recurrent, malignant, or inflammatory groups. No deaths occurred as a result of hemorrhage, wound infection, myxedema, or of tetany.

The causes of death were cardiac insufficiency (1), air embolism (1), pneumonia (1) and postoperative toxic crisis (9). Postmortem examinations showed that of the 9 cases of so-called postoperative toxic crisis there were only 2 in which no pathologic anatomic changes could be found to account for death. In the remaining cases the postmortem examination revealed 2 instances of persistent thymus, 2 of suffocation from laryngeal edema with bloody infiltration of the mediastinum, 2 of toxic coma with bloody mediastinal infiltration and 1 instance of lung carcinoma. The author believes that in many cases of postoperative crisis, and especially when it occurs in nontoxic goiter, there is a hemotoxic histamine-like substance which damages the autonomic cardiac nerves and ganglia and accounts for the bloody mediastinal infiltration.

JOHN L. LUNDQUIST, M.D.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Cerebral Angiography with Ioduron (Angiografia cerebrale con ioduron) MARINO QUARTI TREVANO
Chirurgia, 1947 2 157

The new shadow producing preparation which has recently come on the market is a stable water soluble salt containing 55 per cent of iodine combined as a diiodate of pyridone. It can be injected in 30 per cent solution, and it is much more fluid than thorotrast. No damaging effects have been reported from its use. Following injections into experimental animals no free iodine was excreted through the kidneys. The author has now completed 100 angiographies using this preparation by percutaneous injection into the internal carotid artery. At least 2 injections were made in each subject studied and in a few instances as many as 4 injections were practiced at one sitting. The minimum amount for one injection has been 7 c.c. and the maximum 14 c.c. with a total amount not exceeding 40 c.c.

The patient partially stupefied by oral and intravenous drugs, is placed supine with head extended and the needle is entered over the pulsating artery just below the upper border of the thyroid cartilage. If the oscillations of the needle upon reaching the artery are not perfectly vertical it is considered that the needle has struck the vessel tangentially and the instrument is withdrawn and reinserted at another point. The Ioduron is injected rapidly into the artery as soon as the roentgenologist gives the ready signal. The arteriogram is taken during the process of injection (after 6-6 c.c. have been injected) and the phlebogram exposure is made 2 seconds later.

In the use of this substance by this method in a wide variety of intracranial and intracerebral conditions, the author has seen no bad effects nor has there developed any hematoma or other evidence of harm to the injected artery. Some of the patients complain of facial pain during the injection, however with a co-operative spirit and enough of the drug any incidental discomfort is always tolerated tranquilly. The greater portion of the article is taken up with the production of photographs portraying the wide variety of intracranial conditions demonstrated by this method.

JOHN W. BRENNAN M.D.

Penetrating Wounds of the Cerebral Ventricles.
HENRY G. SCHWARTZ and GEORGE E. ROULHIAC.
Ann. Surg. 1948 127 58.

The author reports an analysis of 50 consecutive cases of head injury with penetrating wounds of the cerebral ventricles. There was a 30 per cent mortality (15 cases) which could be assigned to two factors: infection (60%) and vital brain damage (40%). These cases were verified either at the time of surgery by direct vision or at autopsy.

Thirteen patients were operated upon primarily at an average time of 39 hours after injury. The 4 deaths in this series were all due to vital brain damage. Although infection developed in 2 cases the condition cleared up with adequate surgery. Thirty-six patients were operated upon at forward installations at an average time interval of 15 hours. Thirty-one of these required further surgery—for abscesses in 12 patients, meningitis in 3, and ventriculitis and meningitis in 14. Of the 10 deaths in this series 9 occurred as the result of infection.

The three main factors which enter into the higher mortality of penetrating wounds of the cerebral ventricles are as follows:

1. Introduction of infection with resultant ventriculitis. Incomplete débridement is probably the most important fault.

2. Hemorrhage into the ventricular system. This was not a common finding in the series, however when present it is necessary to remove the clot under direct vision and to verify hemostasis.

3. Injury to vital centers. This group is not amenable to surgical therapy.

Although the treatment is not different from that used in other types of cerebral wounds, it is emphasized that adequate aggressive débridement of the entire tract, including the ventricles, be performed under direct vision. This applies also to secondary cases with abscess or ventriculitis. Chemotherapy and antibiotic therapy was used in various combinations in all cases but they are effective only when combined with the necessary surgery.

JACK I. WOOLY M.D.

The Treatment of Open and Closed Craniocerebral Injuries (Le traitement des traumatismes crâniocérébraux ouverts et fermés) WILLIAM JUMET
Bull. chir. adv. 1947 14 274.

This article from the surgical clinic of the University of Geneva represents the views of the majority of neurological surgeons on head injuries. It is more an abstract of the literature than an experience of the author. As he states the cases are limited but they have been well followed up. There are a few case reports to illustrate the problem and the discussion.

The author discusses briefly and concisely all forms of open and closed head injuries and mentions the opinions of various authorities on these matters. He states that he has considerable difficulty in understanding the conception of concussion or commotio cerebri but declares that of 1,055 cases of head injuries observed at the Clinic for a period of 10 years 527 were commotio cerebri with cure in 87 per cent. Contusion of the brain is discussed with reference to the fact that there is a 10 per cent margin of safety for the brain within the cranial cavity. If the intracerebral contents expand beyond 10 per

cent serious compression will occur because the brain is anchored within the cranial cavity. The 10 per cent augmentation of the volume of the brain interferes with venous drainage with a hypersecretion of spinal fluid which then becomes a vicious circle. Of the 1,033 cases 339 were contusions with cures in 61 per cent and a mortality of 8.6 per cent. Among the suggestions made in the discussion of contusions is that of removing the contused tissue by operation. However the author goes on to say that edema is probably the most important factor. The semisitting position is stressed in the treatment of these cases. The question of extradural hemorrhage is discussed briefly and arteriography is suggested for localization of intercranial hematomas. Mention is made of acute external hydrocephalus.

Open wounds of the brain are mentioned and the conclusions reached with regard to treatment differed very little from those that are commonly now accepted in this country. The skin must be closed over the defect at all costs, with a local application of sulfanilamides and penicillin in cases of primary closure. It is pointed out that it is more important to take the patient to centers where there is special equipment than to turn a general hospital into an ineffective and modified neurosurgical clearing station. The experiences of the British in this matter are discussed. Apparently in Switzerland they are less disturbed when penicillin passes the spinal fluid barrier than we are in this country. The question of dealing with fractures through the accessory sinuses is discussed and apparently operation has not been required in the cases seen at this clinic. Finally the postoperative care of the patient is mentioned with reference to the time at which he should become ambulatory. There seems to be a tendency to keep the patient in bed from 12 to 25 days. The rehabilitation of head injuries is emphasized for it is believed that a useful person should be returned to society not an invalid. The bibliography especially with reference to European authors, is extensive.

ADRIEN VAN BRUGGEN, M.D.

Cerebral Granuloma. TUNO-HO CHANG, GEORGE W. SMITH, F. REGIS RIEFENBERG and EDWIN F. ALSTON. *J Am Med Ass* 948, 136. 30.

The authors present 4 cases of cerebral granuloma caused by *Schistosoma japonicum* eggs which were verified at operation. All patients presented similar neurologic signs and symptoms which pointed to an intracranial space-occupying lesion. In 3 of the patients the granuloma was located in the left hemisphere and produced right-sided hemiparesis, Jacksonian convulsions, and speech disturbances. Only one patient showed obvious signs of increased intracranial pressure. Air studies confirmed the diagnosis of intracranial tumor in each case. In 2 of the patients a slight increase in the blood eosinophils (6 and 12%) was reported, together with a slight increase in the spinal fluid lymphocytes. The pathological examination of the tissue removed at operation

revealed numerous pseudotubercles which contained in their center nests of eggs of *Schistosoma japonicum* and giant cells. They were walled off by dense collagenous fibrous tissue and a zone of diffuse lymphocytic infiltration. The patients were given stibophen postoperatively and showed continuous but slow improvement in their condition.

These patients had all seen service in the South Pacific or the Philippine Islands, but none gave a history relative to an acute phase of schistosomiasis prior to the development of cerebral symptoms. The authors outline the life cycle of schistosoma, review their classification, and the differential diagnosis of their species on the basis of the appearance and size of the eggs and the geographical foci of infection. They discuss also the symptoms produced by the three clinical stages of infection in man. They believe that the cerebral symptoms are the result of the reaction produced by the deposit of eggs which reaches the brain after passing through the vertebral venous system or the accessory portal circulation.

The literature on cerebral schistosomiasis and its medical and surgical treatment is reviewed and the authors recommend craniotomy as an adjunct to the medical treatment when there is evidence of a localized expanding lesion. Cerebral schistosomiasis may appear clinically several months, or even several years, after the primary invasion by the larval form. The disease seems to be far more common than previously suspected. A history of early systemic schistosomiasis is not necessary for the diagnosis of the cerebral form which should be suspected if the patient has been exposed to the disease in regions in which it is endemic.

GEORGE PRINCE, M.D.

Contribution to the Study of Intracranial Cystic Neurinomas (Contributo allo studio dei neurinomi cistici intracraniali). EUGENIO PATELLANI. *Chirurgia*, 947, 2-113.

A subdural cystic neurinoma of the spinal cord in a 39 year old woman was studied by the author histologically. The tumor was located at the level of the eleventh dorsal vertebra and produced an incomplete block of the subarachnoid space. The tumor was successfully removed and the patient recovered.

The tumor was encapsulated and highly vascular. In addition to fibrocellular areas there were fibrillary cells of immature character. From the histomorphologic point of view the dual composition of the tumor and the staining properties of the fibrillary portion justified the diagnosis of neurinoma of the Verocay Antoni type or neurofibroma or perineural fibroblastoma of the Mallory Penfield type. The mesenchymal histogenesis of the tumor could thus be established.

The formation of cavities or lacunae is ascribed by the author to edematous imbibition of the immature cellular formations caused by a sudden increase of pressure of the cerebrospinal fluid and also by necrosis of the intercystic septa. The last mentioned proc-

was conditioned by vascular disturbances probably was responsible for hemorrhages within the cavities.

A rapid increase of the size of the tumor undoubtedly was responsible for the neurologic syndrome of irritation and compression.

JOSEPH K. NARAT, M.D.

The Treatment of Facial Paralysis by Tantalum Wire Suspension—Preliminary Report. LOUIS W. SCHULTZ and EDSON FAIRBROTHER FOWLER. *Plast Reconstr Surg.*, 1947, 2: 538.

A preliminary report of a modification of Schussler's tantalum wire suspension technique employing sheet tantalum saddle and the authors' technique with tantalum gauze is presented as another addition to the surgery of facial paralysis and to the use of tantalum in plastic surgery.

Various methods employed in the surgical correction of facial paralysis by Busch, Momborg, Stein, Blair, Gillies, and Schussler with the use of wire of several varieties, fascia, and fascial slings are briefly reviewed with particular emphasis on the disadvantages of each in comparison to Schussler's method. The last technique has certain faults which the authors believe they have overcome with the use of tantalum gauze.

The surgical technique of an operation performed in two stages is described. In the first stage a pattern of tantalum gauze is set in the affected cheek and entirely across both lips. Fibrous bands growing through the gauze mesh firmly fix these parts. In about 2 months the second stage of the operation is performed. This consists of suspension, by means of tantalum wire, of the tantalum gauze fibrous tissue. The wire is placed through the superior margin of the gauze in the cheek and connected with a tantalum gauze sheet fixed to the temporal fascia by tantalum wire. The postoperative care is described.

A series of 3 cases is presented with before and after pictures and one roentgenogram showing the tantalum gauze and wire in position postoperatively.

EARL H. KLABONZ, M.D.

SPINAL CORD AND ITS COVERINGS

Pseudohypertrophic Sclerosis of the Yellow Ligaments, a Cause of Compression of the Cauda Equina (Sclerosi pseudo-ipertrofici dei legamenti gialli causa di compressione della coda equina). CARLO FAIS. *Chir. org. movim.* 1946, 30: 261.

In this article, cases of pressure on the cauda equina resulting from pseudohypertrophic sclerosis of the yellow ligaments are reviewed. In addition, the author reports 2 cases proved at operation and by subsequent histological examination of the tissues removed at the time of operation which were observed during a series of 100 laminectomies performed for various reasons at the Rizzoli Institute of Bologna.

At the time that this article was accepted for publication June 27, 1944, the author could collect only 52 similar cases, 43 of which had been reported

by North American authors and only 9 reported by European authors, none of the latter in Italy.

After presenting his 2 cases, the author discusses at length the anatomy, histology, and physiology of the yellow ligaments and the etiology, concomitant lesions, anatomopathological picture, pathogenesis, subjective and objective symptoms, diagnostic signs and treatment of this condition.

The first case reported by the author was that of a 40-year-old male who entered the hospital on August 28, 1940, complaining of backache of several years' duration. Following a motorcycle accident on April 21, 1927, he had suffered constant lancinating pains in the lumbar region and was unable to bend or straighten his trunk. This painful contraction of his trunk was severe and caused him to remain in bed for a week. Following the application of heat, the pain gradually diminished and he was able to return to work. During the next 12 years he experienced three similar attacks of lumbar pain without apparent cause, each attack lasting about one week and being relieved by the application of heat and rest in bed. In the interim between attacks the patient was bothered by constant weakness of the lumbar spine and pains of varying intensity upon even slight exertion. Spinal movements were limited.

August 15, 1938, the patient experienced another attack which was not relieved by rest in bed, application of heat, or the wearing of supporting girdles and corsets. The pain finally became localized over an area the size of the palm of the hand in the right paravertebral space at the level of the first sacral vertebra. Bladder and sexual functions were normal.

Physical examination revealed an athletic type of person with a very noticeable rigidity of the lumbar spine accompanied by a physiological lordosis. Pain was experienced on pressure over the right paravertebral space at the level of the first sacral vertebra and the right sacroiliac joint. Sitting and erect postures were painful, but most pain was experienced when the patient was in a horizontal position.

Neurological examination revealed no motor disturbances. There was hyposenitivity to heat in the skin of the fifth lumbar and first sacral segments on both sides. The left knee jerk was absent and the left Achilles reflex was hypocoactive. Other reflexes were normal. Jugular pressure, cough, and deep inspiration provoked slight lumbar pain. There was no muscular atrophy.

Roentgenography of the spine revealed diffuse calcification of the lumbar spine, the articular apophyses were owl beaked, and the space between the fourth and fifth lumbar vertebrae was narrowed.

Spinal puncture revealed normal fluid under normal pressure.

A myelogram, after the injection of lipiodol solution, revealed a descent of the opaque fluid to the normal distal limit with fragmentation of the opaque shadow at the levels of the last three lumbar vertebrae. With the patient in the Trendelenburg position there was a filling defect at the level of the fourth lumbar vertebra.

Laminectomy was performed on September 12, 1940 under local anesthesia. The yellow ligaments at the level of the fifth lumbar vertebra were found tenaciously adherent to the dura and so abnormally thickened that it appeared as if they were a separate tube.

Postoperative convalescence was normal and post operative results were satisfactory.

Histological examination of the yellow ligaments removed at operation showed a 2 mm thickening and the ligaments were composed chiefly of dense fibrous tissue and collagen fibers. Elastic fibers were sparse and diffuse. Many blood vessels had been obliterated. Large hyaline and calcareous deposits were scattered throughout the connective tissue. A histological diagnosis of pseudohypertrophic sclerosis of the yellow ligaments was made.

The second case reported by the author was that of a 43 year old male, who entered the hospital on August 4, 1941 with a past history of sciatica on the left side at 25 years of age without any relation to injury which was cured after a few weeks of medical treatment. Fifteen months before entry without apparent cause the patient began to notice lumbar pain with radiation to the left buttock. Eight months before entry the pain had spread to the whole left lower extremity. The pain was accentuated by lateral and anterior movements of the spine, and by the supine position. Six months before entry extension of the left knee became limited and a month later motor weakness of the entire left lower extremity developed.

Physiotherapy, x-ray therapy and local injections of various kinds had no effect on the disease.

Physical examination revealed a well developed adult male with rigidity of the lumbar spine and a slight deviation of the spine to the right, the convexity of the curve being to the left. There was pain on palpation with radiation of the pain to the left sciatic nerve. There was atrophy of the left lower extremity.

Neurological examination revealed, in addition to the motor weakness tactile and thermal hypesthesia of the anterolateral aspect of the left leg and foot. Reflexes were normal except that the left Achilles reflex was sluggish and the left plantar reflex was absent.

X-ray examination revealed sacralization of the fifth lumbar vertebra and lumbarization of the twelfth dorsal vertebra.

There was a reaction of degeneration of the muscles supplied by the nerves from the fourth and fifth lumbar roots. No electrical conduction occurred through these nerves.

Lumbar puncture showed normal fluid under normal pressure.

The myelogram, after lipiodol injection showed a defect of the opaque medium at the last lumbar interspace and with the patient in the Trendelenburg position there was a partial block between the fourth and fifth lumbar and the fifth lumbar and the first sacral vertebrae.

Laminectomy of the fourth and the fifth lumbar vertebrae under local anesthesia revealed a thickened yellow ligament with stenosis of the dura in the lumbosacral region. There was no herniation of the discs. The thickened ligament was removed to relieve pressure on the nerve bundles.

Postoperative recovery was uneventful and the lumbar and sciatic pain disappeared in a month. There was residual rigidity of the spine and permanent paralysis of the small sciatic, peroneal, and anterior tibial nerves.

Histological examination of the specimen of yellow ligament removed at operation showed a thickness of 8 mm. The ligament was composed of fibrous tissue and irregular collagen fibers with sparse elastic fibers, hyaline degeneration, and obliterated blood vessels. Diagnosis of pseudohypertrophic sclerosis of the yellow ligaments was made.

After a lengthy discussion of the anatomy of the yellow ligaments, the author concludes that the interlaminae portion of the yellow ligaments with the nerve roots is situated within the dura and is bathed in the spinal fluid while the interpeduncular portion with the ganglia is covered by the dura, but not by the arachnoid, and therefore it is not in contact with the spinal fluid. Eventual hypertrophy of the yellow ligaments can compress contemporaneously one or more bundles of the cauda equina or isolate a ganglion and cause a change in the spinal fluid to some degree.

The yellow ligaments have a characteristic color because they are made up almost entirely of elastic tissue, differing from other ligaments in this respect. The elastic fibers, from 5 to 6 micra in size appear in closely packed bundles. They lie chiefly in a vertical plane in the interlaminae portion and in an oblique plane in the interpeduncular portion but the fibers intersect transversely. Collagen fibers are sparse and the blood vessels are imbedded in the small amount of connective tissue that appears in the ligament.

The chief characteristic of the yellow ligaments is their elasticity. This characteristic enables the ligaments to perform an important part in stabilizing the vertebrae and aiding in the movements of the spine. When the nucleus pulposus, under tension, tends to separate the vertebral bodies, the elasticity of the yellow ligaments tends to bring together the laminae with the intervertebral articulations as a fulcrum. The nuclei pulposi of the intervertebral discs and the yellow ligaments have a synergistic action. When the spinal column is flexed the nuclei pulposi are displaced posteriorly and the yellow ligaments extend vertically when the spinal column is extended, the nuclei pulposi are displaced anteriorly and the yellow ligaments are drawn backward. In the lateral movements of the spine the nuclei pulposi move slightly to the side of extension and the yellow ligaments of the same side stretch, while those of the opposite side contract. In twisting movements, the nuclei pulposi form a hinge and the yellow ligaments stretch obliquely and laterally.

thus they contribute to the restoration of the normal position of the spine after each movement.

The condition under consideration occurs in individuals from 16 to 57 years of age according to the cases reported with the highest incidence in the fourth decade. It occurs more often in men than in women—in the ratio of 3 to 1. Both of the author's cases occurred in men in the fourth decade. The most common site of the hypertrophy is between the fourth and fifth lumbar and the fifth lumbar and the first sacral vertebrae. Hypertrophy most often occurs in the interlaminar portion with the syndrome of compression of the roots of the cauda equina, and less often in the interpeduncular portion. Indirect trauma is the determining factor in 75 per cent of the cases.

Concomitant lesions are blemishes of the discs eventual thickening of the laminae at the insertion of the hypertrophied ligaments disintegration of the bodies of the vertebrae from fracture or neoplasm, and laceration of the yellow ligaments in cases of severe trauma.

The anatomopathological picture is one of atrophic sclerosis of the yellow ligaments with a stenosing action of the dural sac. The thickening of the ligament may vary from one to four times the normal thickness. Grossly the ligament appears a brilliant white because of the substitution of the normal elastic tissue by connective tissue. It becomes tenaciously adherent to the dura the epidural vessels are compressed, and the subsequent edema gives rise to a compression neuritis. Microscopically, the elastic fibers become disorganized and are later replaced by connective tissue. The blood vessels in the ligament become obliterated by hyaline and calcium deposits are laid down and fatty degeneration is also present.

The first and most important symptom is acute lumbar pain following trauma in most cases which persists and increases in severity but in some cases the pain diminishes only to be followed by more frequent and severer attacks of pain after the slightest trauma. As the disease progresses and pressure is exerted on the nerve bundles of the cauda equina, the pain becomes referred to progressively descending parts of the lower extremity. Signs of motor damage may appear later.

Neri's sign that of lumbar and sciatic pain induced by forced flexion of the head on the thorax with the patient in the supine position can be elicited. Neri's sign is the most important sign of hypertrophy of the yellow ligaments as well as of hernia of the discs. This sign is demonstrated when compression of the jugular vessels elicits pain in the lower back. When nerve involvement has occurred the localized reaction of degeneration can be demonstrated. Heterological scoliosis with the convexity of the curve to the painful side often occurs. Painful contracture of the trunk and lower extremity with inability to completely extend the knee joint occurs when the pain is severe and long continued. Hypoesthesia of the anal and sacral regions and of the

anterolateral aspects of the leg and foot may occur. X-ray examination, following lipiodol injections into the subdural space reveals deformities resulting from pressure of the hypertrophied ligaments which causes partial or complete block.

Physiotherapy x-ray therapy and immobilization by means of corsets and braces are only of temporary benefit. Barring contraindications relief is obtained from laminectomy with removal of the pressure of the hypertrophied ligaments on the nerve bundles of the cauda equina. The site of operation is determined by myelography after lipiodol injections. Local anesthesia is used in most cases.

Postoperative results are good and the subjective symptoms and objective signs disappear rapidly after surgical intervention.

BLACKWELL MARKHAM, M D

Spinal Extradural Cyst: Report of a Case, with Particular Reference to a Possible Diagnostic Aid OSCAR A. TURNER. *Arch. Nerv. Psychiat. Chic.*, 1947 58 593.

The author reports a case of spinal extradural cyst in an 11 year old boy with progressive loss of power in the lower extremities over a period of 5 months. A spastic paraplegia was present with a sensory level at the ninth thoracic segment. Roentgenograms revealed enlargement of the vertebral canal chiefly in the region of the seventh and eighth thoracic vertebrae. There were erosion and atrophy of the pedicles and erosion of the posterior margins of the bodies of the affected vertebrae.

Spinal puncture revealed evidence of a complete block with xanthochromic fluid. After withdrawal of 4 c.c. of fluid improvement in motor function of the legs was noted an hour and a half later.

At operation a large extradural cyst was removed which showed direct communication with the subarachnoid system through a small defect in the dura. Pathological study revealed the wall of the cyst to be composed of a double layer of rather heavy collagenous tissue, which was partly hyalinized. Between the inner and outer connective tissue layers forming the wall of the cyst was a layer of tissue formed either by a bank of cuboidal or flattened cells or by a mesh of elongated and stellate cells with interlacing processes.

The author believes that this represents a case of extradural spinal cyst associated with early roentgenologic manifestations of kyphosis dorsalis juvenilis and erosion of the pedicles.

He points out that the improvement in function of the lower extremities resulted from partial evacuation of the cyst, because of its communication with the subarachnoid system, and that this may be a useful sign diagnostically.

Anatomic evidence has been presented to show that the origin of the cyst is a herniation of the pia arachnoid through the dura, and chemical analysis of the fluids in the cyst and in the subarachnoid space would indicate that the fluids are identical.

HOWARD A. BROWN M D

PERIPHERAL NERVES

The Problem of Surgical Therapy in Lesions of the Peripheral Nerves (Il problema della terapia chirurgica nelle lesioni dei nervi periferici) E. MINZKOWSKI and U. SACCHI. *Chirurgia*, 946, 407

It was noted that in late operations, that is, any time after a month from the time of injury the time required for recovery is about the same as when it is done earlier. For injuries to the tibial or peroneal nerves this ranges from 13 to 15 months.

To explain this phenomenon the theory is propounded that the regenerative process after a certain time must start from the trophic end of the cord and from thence advance down toward the point of injury at the rate of about a mm. per day just as pointed out by Cajal and others. A graph is presented which shows that in the cases in which there was a failure of regeneration the operation had not been done up to the time that this slowly advancing regenerative process reached the point of interruption of the nerve. The authors believe, therefore, that the nerve can be operated upon too late. Of course no definite period can be fixed for the operation of nerve suture; it will vary with the nerve injured, with the physical characteristics of the injured individual and with the level at which the nerve injury is located. The nearer the injury to the trophic center in the cord and the more proximal its location the earlier the operation must be done.

By observation of these limitations the operation of nerve suture can generally be expected to produce satisfactory results as far as procuring a return of contractile power to the larger muscles. However it has been abundantly demonstrated that the smaller muscles, such as those of the hands and feet, soon lose their capacity for regeneration whether this be due to a disappearance of the motor end plates or to early infiltration of connective tissue.

It would seem advisable to operate early on such nerves as the ulnar, peroneal or tibial in order to give them the chance to start regenerating from the point of injury instead of from the trophic center. Therefore the authors divide their cases into 2 groups: (1) those suitable for early suture of the nerves supplying small muscle groups and (2) those in which suture should be done after the second month when the process of regeneration has failed to respond in the manner described for the early operative case.

JOHN W. BRENNAN, M.D.

The Use of Autogenous Grafts for the Repair of Large Gaps in Peripheral Nerves. H. J. SKIDON. *Brit. J. Surg.* 1947 35 5

Extensive loss of nerve tissue presents one of the most difficult problems in the repair of peripheral nerve injuries. In the author's series of 699 cases requiring operative repair it was found that 8.6 per cent of the patients had lesions that were repairable only by the use of nerve grafts. Despite occasional case reports on the successful use of both hetero-

nous and homogenous grafts, it is the unequivocal opinion of the author that such grafts are not of the slightest use in clinical practice; hence only the use of autogenous nerve grafts offers any hope for recovery in these cases.

The present report is based upon the results obtained in 58 cases in which nerve autografting had been performed. There are several technical considerations that must be borne in mind in treating such injuries. A basic factor that has received scant attention in the past is that the graft, or collection of grafts, must have a total cross section area at least equal to that of the peripheral nerve to be repaired. This should apply both at the proximal and distal portions since it is obvious that if the nerve graft is smaller at one end it is not likely that the entire number of regenerating nerve elements would be able to pass through the graft.

In the use of cutaneous nerves, one should ascertain that there are no bifurcations of the nerve during its course. Four specific cutaneous nerves were found to be of exceptional value. These are as follows: the internal cutaneous nerve of the forearm proximal to its bifurcation at the elbow, the superficial radial nerve, the sural nerve, and the saphenous (internal saphenous) nerve in the thigh. Although there have been theoretical objections to the use of cutaneous nerves in the repair of nerves in which motor fibers might be anticipated, these have been completely dispelled by the present series. A segment of the trunk of a main nerve may be used very satisfactorily when two large nerves are damaged and it is considered possible to repair only one. Although there is a definite risk in the use of large nerve grafts because of the possibility of ischemia with resulting collagenization, it is nevertheless a worth while procedure. It is possible that Strange's pedicle grafting technique will prove the solution to this problem. Predegenerative grafts have also been advocated; however the author is not completely satisfied with this theory.

The operative technique in nerve grafting of autogenous nerves is essentially similar to that for other nerve suture; however there are several factors which require emphasis. In cases of severe cutaneous scarring it is usually advisable that the repair be made by plastic surgery with the use of full thickness flaps before performing the definite nerve repair. At this time it is usually possible to determine what type of nerve repair will be required. Mobilization of the nerve stumps may be carried out if the defect is so great that a sufficient supply of graft material may not be obtainable. However in this case, it must be remembered that extreme flexion of the joint or marked stretching of the nerve is not advisable. Flexion of the knee or elbow beyond 90 degrees is considered hazardous. Resection of the end bulb should be carried out similarly to that in any other type of nerve repair. There is seldom any difficulty in resection of the proximal bulb since the existence of the neuroma itself is indicative of healthy axons. The distal nerve stump requires much more exten-

sive resection since collagenization may extend for a considerable distance. The bed for the graft should be in a healthy vascularized area. If there is extensive scarring, it is worth while to consider the by-pass operation in which case the nerve is either tunneled or placed through healthy tissue. Since it is now well recognized that grafts shrink it is advisable to secure a graft at least 15 per cent longer than the gap to be closed. If at all possible a graft from a distal stump should not be used especially if an injury has occurred more than 6 months previously.

The author stressed the need for a meticulous and precise technique in suturing of the nerve. Since the handling of cutaneous nerves is extremely tedious and hardly permits of satisfactory suturing with thread the author prefers the use of the plasma clot fixation. He has not found the use of the molds as devised by Tarlov convenient. Instead he builds up the surrounding area by the use of either bone wax or fibrin foam to make a small lake about the area to be sutured, and pours in the prepared plasma following which the bone wax or fibrin is removed.

An evaluation of 52 of the 58 cases that had been followed sufficiently long to permit a fair assessment reveals that in 20 cases (38.5%) recovery was as good as that following end-to-end suture. Seven patients were showing satisfactory recovery although their end result was not fully evaluated. Partial but useful recovery had occurred in another 8 cases which made the operation of the autogenous nerve graft a valuable procedure in 67.3 per cent of the cases.

SYMPATHETIC NERVES

Sympathectomy for Obliterative Arterial Disease; Indications and Contraindications. NORMAN E. FREEMAN, FRANK H. LEXES and RICHARD E. GARDNER. *Ann Surg.*, 1947 126 873.

It is well recognized that sympathectomy is useful in the treatment of peripheral vascular disease when associated with vasospasm and abnormal vasoconstriction. Although verification of the vasospastic elements by preoperative diagnostic tests is helpful, lasting and progressive improvement may be attained even when these tests fail to reveal satisfactory results. Since vasodilator tests may not allow sufficient time for maximum effect, great reliance has been placed upon the subjective improvement after such tests.

Clinical tests have been utilized by the authors in the selection of patients with intermittent claudication for sympathectomy but they emphasize the importance of the presence of the following signs of abnormal vasoconstriction: (1) peripheral cyanosis, (2) increased sweating and (3) constriction of superficial veins of the extremity. Delayed blanching on elevation of an extremity is also of significance. Whether this is due to venous constriction and concomitant arterial constriction remains theoretical.

A contraindication to sympathectomy that has failed to receive widespread recognition is advanced obliterative arterial disease. In such cases delayed gangrene may ensue. The authors discuss the cases of 4 patients who developed gangrene. The following frequent contraindications were noted: (1) pain due to ischemic neuritis, (2) rapid blanching on elevation, (3) absent oscillations at the ankle and (4) atrophy of soft tissues.

The unusual site of the gangrene (on the dorsum of the foot) is somewhat similar to that following proximal ligation of a major artery in the presence of an arteriovenous fistula. In this case there is a precipitous drop in the pressure due to a greatly expanded vascular bed on the venous side. In advanced obliterative vascular disease the major arteries are already blocked hence destroying the vasomotor tone of the arteriovenous anastomoses permits the blood to be abruptly shunted into the venous system.

JACK I. WOOLF, M.D.

An Anatomic Evaluation of Operations for Hypertension. G. A. G. MITCHELL. *Edinburgh M. J.* 1947 54 545.

In view of the increasing evidence of the value of sympathectomy in the treatment of hypertension and because of the widespread variance and extent of the operation as it is being performed the author believes that its evaluation on anatomic grounds is indicated at the present time. In order to make this evaluation however it is necessary to determine what effects are desired. The consensus of the various authorities who have performed the greater number of these operations is that the attempt should be made: (1) to produce widespread vasodilatation of the greater part of the abdominal splanchnic area, (2) to denervate the vessels of the lower limbs in order to produce somatic dilatation in these parts, (3) to denervate the kidneys in order to intercept possible reflex vasoconstrictor impulses and (4) to denervate the suprarenal glands to diminish the secretion of adrenaline and to prevent vasoconstriction of the suprarenal vessels.

There are certain basic requirements or factors which must be kept in mind when considering the type of operation that is necessary to produce the aforedescribed effects since they may also influence the type of operation or procedure selected. First of all the operation must carry a minimal risk to life which is consistent with the production of the desired results. It should also produce as few undesirable sequelae as possible. It should be sufficiently extensive to prevent nerve regeneration and should be preganglionic rather than postganglionic in type. The incision for the operation should allow exploration of the renal, suprarenal and paravertebral areas in order to rule out the possibility of associated tumors in these regions which may be a possible cause of the hypertension.

The variability of the peripheral distribution of the sympathetic nerves must influence the extent of the operative procedure since it has been shown that the

escape of only a small proportion of the nerve fibers supplying certain viscera or vessels may produce effects entirely disproportionate to their numbers.

Fifty four dissections were performed. In 8 specimens, nerve rootlets of the greater splanchnic nerves arose at a level as high as the fourth thoracic ganglia, and in one case, as high as the third thoracic ganglia. Many of the upper rootlets supply the aortic and esophageal filaments and some of these may pass downward to the abdomen along the aorta and hence escape in the ordinary thoracodorsal sympathectomy. In approximately 10 per cent of the dissections a para-aortic nerve was seen. Occasionally this nerve had upper fibers arising as high as the fourth or fifth thoracic ganglia.

The author suggests that the optimum sympathectomy required for the treatment of hypertension should be a bilateral resection of the sympathetic trunks from the fourth ganglia to the third lumbar ganglia with removal of all the splanchnic nerves, since only an operation of this magnitude will satisfactorily denervate the desired areas or those considered necessary by the majority of investigators. Nevertheless it is realized that even an operation of this extent may allow the escape of certain sympathetic nerve filaments. JACK L. WOOLF, M.D.

MISCELLANEOUS

Post Traumatic Osteoporosis Algica or the Syndrome of Sudeck, Treated by Novocainization of the Stellate Ganglion (Osteoporosis algica post traumática o síndrome de Sudeck, tratada por novocainización del ganglio estelar) ISIDORO PASCAO CIR. CRISTÓBOL MEL, Habana, 946 33

One hundred and thirty-three cases of Sudeck's syndrome are reported. Of these 93 (70%) resulted from a Colles fracture the rest represented various fractures of the bones of the forearm, wrist and

hand. 4 were displaced fractures of the surgical neck of the humerus and 1 was a partial and another a total avulsion of the greater tuberosity of the humerus. The last was accompanied by dislocation of the shoulder joint which had remained unreduced for 48 hours following the injury. The remaining cases were instances of woundings and infections.

Treatment consisted exclusively of novocainization of the stellate ganglion by the technique described by Debaquey-Ochaner with a slight variation. By this method the ganglion was blocked once or twice a week, and a total average of 15 injections was given. Of course preventive measures, especially in these fracture cases, should be carried out. In any case of fracture in which the fingers become cyanotic, seem to be losing mobility and flexibility or in which edema appears, the cast should be loosened or the hand freed especially in the Colles fracture, the extremity should be elevated, and active exercises, such as the crinkling together of a silk handkerchief or the squeezing of a partially inflated rubber ball should be initiated.

However when the syndrome is definitely established the author uses only the method of novocainization of the stellate ganglion in the neck and then stimulates active movements. For the latter purpose he uses a special stimulus to muscular recovery in the guise of ionization treatments with methohyl or another acetylcholin derivative. The pain and muscular debility disappear sooner than the roentgenographic changes in the bones.

The author believes that the novocainization method is equal to or better than excision of the stellate ganglion as it does not leave a lasting Horner's syndrome in its wake. No deaths and no serious complications have been observed with this method. The only troubles noted were a slight transitory aphonia, nausea, dizziness and some sensation of oppression in the chest. JOHN W. BRENNAN, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Malignant Myoblastoma of the Mammary Gland
(Sul mioblastoma maligno della mammella) Virro
Lorizio *Gior ital chir* 1947 3 486

A 36 year old woman noted a small tumor in the upper outer quadrant of her left breast 6 months before she presented herself. When first seen the mass was the size of a large orange. It was covered by a tensely taut skin which could not be raised in folds and showed a moderate amount of venous marmoration. The neoplasm was of a densely elastic consistency and was not painful to palpation. It could not be displaced on the underlying tissues. The breast itself was freely movable. A diagnosis of adenocarcinoma was made and the breast and axillary lymph glands were removed en bloc. One year later the new growth had recurred in the guise of a slightly mobile, dense hazelnut-sized tumefaction in the healed scar of the original operation. The recurrent mass regressed under the application of roentgen therapy.

Histologic examination disclosed even under low power of the microscope a cell rich parenchyma with meager connective tissue stroma extending in a diffuse manner among the tumor cells. These cells varied greatly in size and shape and in their number of nuclei. There were numerous small, rounded fusiform cells disposed in featureless masses or tending to arrange themselves in what resembled bundles reminiscent of bundles of muscle cells. Even in these smaller cells there was evidence in places of longitudinal striation. The larger cells were often giants, even larger than the Langhans cells of tuberculous granulomatous tissue. These huge cells had usually more than one nucleus (from 2 to 15). The nuclei varied in size in position in the cytoplasm of the cell in their content of chromatin (usually in excess) and in the number of nucleoli. The polymorphism of these cells defies detailed description; however there were numerous square forms or forms drawn out in bandlike structures with a thick cell membrane along the longer side, the shorter side being practically without cell membrane, as though it were broken off abruptly. The voluminous cytoplasm in these cells was definitely eosinophilic and there was vague or definite evidence in the cytoplasm of longitudinal striation. There were ribbonlike bands resembling the cytoplasm of the aforementioned giant cells, but without nuclei. When nuclei were present, they were usually elongated and disposed along the periphery of the cell as a rule along the longer side and frequently on alternating sides. There were also huge cells of rounded shape or in the shape of a palette, that is, with a rectangular or bandlike process extending from the main cell mass. These processes never contained nuclei but were especially rich in longitudinal striations.

With a stain of sierra-orange these giant cells were found to be particularly rich in salts of potassium. The lymph glands from the axilla gave no histologic evidence of metastasis.

This tumor is considered a malignant myoblastoma in accordance with the classification given in Tonelli's recent study of this subject (*Arch Vecchi* 1943 vol. 595)
JOHN W BRENNAN M.D.

Testosterone in the Treatment of Breast Carcinoma. FRANK E. ADAMS. *Med. Clin. N. America* 1948 32 18.

The author prefaces his article with a discussion of the literature on the treatment of cancer of the breast with androgens. The first reports of cases in which this method of treatment was used were presented in 1939, by Loesser, Ulrich, Farrow and Woodard, and Fels, Prudente and Bolger followed with reports of varying success in the treatment of carcinoma of the breast with this substance.

Testosterone has been used in many forms. The propionate and acetate forms are administered in transmuscularly crystalline pellets by subcutaneous implantation and methyl testosterone is given orally.

Loesser suggests the possibility of forestalling the reappearance of cancer in patients in whom all known breast neoplasm has been eliminated. He cites one case in which no beneficial effect from the testosterone was obtained but it seemed to influence the eventual favorable response to roentgen therapy. The adverse effects are limited to hypercalcemia.

The present report is based on the author's experience with testosterone therapy in 450 cases of carcinoma of the breast. Following the implantation of 300 mgm. of testosterone there resulted skipped menstrual periods, hirsutism, deepening and huskiness of the voice, an increase in sexual desire, and acne. Besides this virilizing effect and the improvement in general health, testosterone exerts a direct and an indirect effect on cancerous tissue. There may be a diminution in size of the primary or metastatic tumors. In bone metastases, the improvement may be direct or indirect because of sclerosis at the site of the metastasis or in the osseous system as a whole.

Instances of improvement are much more common and striking in bone metastases than in soft tissue recurrences. Following testosterone therapy the entire osseous system becomes more dense, the local areas of destruction often fill in with bone salts with frequent restoration of trabeculae and contour. These changes have been observed in the roentgenogram. While local lesions may undergo complete repair, other bony lesions may not be influenced and may continue to increase. Two cases are reported in which patients with bone metastases obtained relief for a period of 3 years.

The author believes that we now have an agent that is capable of prolonging the life of the patient,

in fairly good condition for 3 years at least. With further experience in the use of hormone therapy, palliation may be obtained for a longer period of time. Usually the patient begins to feel relief of pain after from 3 to 5 weeks of hormone medication. The author presents the case of a patient with abdominal metastases who showed remarkable response to testosterone therapy. Little improvement in liver and chest metastases has been observed.

The author favors a plan of dosage whereby the patient receives 100 mgm. of testosterone propionate intramuscularly three times a week for a period of 10 weeks, following which a maintenance dose of 40 to 60 mgm. daily of methyl testosterone by mouth is given for 8 weeks. Enough hormone to inhibit estrogenic action should be given this amount remains to be established.

There are no contraindications to testosterone therapy in patients with advanced cancer of the breast. In general, the results which may be anticipated following androgen therapy are: relief of pain, removal of disability, increased appetite, weight gain, ability to sleep without the aid of narcotics, delay in the normal growth processes of metastatic cancer and a feeling of well being. Even though the results are frequently disappointing, it is believed that the influence of testosterone on mammary carcinoma is so striking that clinical and metabolic studies should be pursued with vigor.

ROBERT R. BICKLOW, M.D.

The Relationship Between the Stage of Tumor Development and Age in Determining the Prognosis of Breast Cancer (Die Abhängigkeit der Prognose der Mamma-Carcinome vom Tumorstadium und vom Lebensalter anhand von 703 Fällen) H. R. SCHNITZ and Ch. BORRESEN. *Acta radiol. Stockh.*, 1947, 25: 611.

Of 1,033 malignant lesions of the breast seen at the Institute of Radiation Therapy in Zurich between 1919 and 1945 703 have been carefully classified according to the classification of Schlims and Steinthal. These have been related to the ages of the patients, and several facts are brought to light. In the authors' experience, younger women presented themselves more frequently in the early stages of the disease, while older women more frequently presented themselves with wholly inoperable lesions. In the younger women small tumors appeared to give rise to metastasis earlier than in older women. The cases of advanced local lesions with no metastasis occurred almost exclusively in older women.

In a small number of patients almost all older women, there was a tremendous local infiltration without any metastasis and with a relatively very good prognosis. However when the same stages of tumor development are compared the results are identical in the older and in the younger women. By a careful classification on a purely clinical basis, it was possible to estimate the chances of cure within from 10 to 30 per cent. WILLIAM C. BICK, M.D.

Follow Up Examination of 103 Cases of Cancer of the Breast with the Purpose of Evaluating Preoperative and Postoperative Irradiation Therapy (Examen ultérieur de 103 cas de cancer du sein en vue de l'appréciation de la radiothérapie pré et post-opératoire) M. ANDERSEN. *Lancet*, 1947, 4: 702.

This material originating from the surgical clinic of Dahl Iversen in Copenhagen, Denmark, is divided into three parts according to the method of classification by Steinthal, the first consisting of 29 patients with a small nonadherent primary tumor and absence of metastases in the axillary lymph glands; the second of 42 patients with a moderately sized tumor and invasion of the axilla; and the third of 32 patients with a large, rapidly growing tumor adherent to the skin or underlying muscle or to both, and with metastases in the axillary lymph glands.

All of the patients were given postoperative irradiation treatment and every other one was given preoperative roentgen therapy in addition. Preoperative treatment consisted of 3,000 roentgens given through 3 portals and in 3 weeks' time. The patients were operated upon after 4 weeks. The postoperative therapy was started about 2 weeks after the operation and again consisted of 1,000 roentgens per portal for a total of 3,000 roentgens.

The material was rechecked 3 years after operation and again after 5 years. In the period between the third year and the fifth year recurrences developed in 15 per cent, which showed that the period of observation of 3 years is not long enough to postulate a cure. Of the original material of 103 patients all were living at the end of 5 years except 4. These apparently did not die of their cancer. Of the 99 remaining patients 38 per cent did not show any evidence of recurrence at the end of 5 years. However there were only 3 recurrences in group 1, 28 in group 2 and 30 in group 3.

The great importance of the invasion of the axillary lymph glands is emphasized. Of the 29 patients in whom these glands were not involved 24 (80 per cent) remained without recurrence while among the remaining 70 there were only 24 (10 per cent) who were free from recurrence at the end of 5 years. Another important observation on this material is that 51 per cent of the recurrences took place in the supraclavicular lymph glands; this argues for extension of the operative field in cases of this type.

No definite evidence could be obtained from this material that the results to be expected from combined preoperative and postoperative irradiation therapy are any better than those from postoperative therapy alone. JOHN W. BRIDGES, M.D.

TRACHEA, LUNGS, AND PLEURA

Surgical Aspects of Bronchiectasis. JOHN W. STUEBEL. *N. England J. M.* 1948, 238: 90.

The definitive treatment of bronchiectasis is surgical excision of the involved segments if their total extent is not excessive.

The results of medical management are reviewed on the basis of numerous series. Medical treatment was found to be inadequate. A summary of the collected data on medically managed bronchiectasis indicated that less than 10 per cent of patients with severe bronchiectasis obtain a satisfactory result, and that the mortality in from 10 to 15 years after diagnosis is between 30 and 50 per cent.

The improved technique of pulmonary resection by individual treatment of the hilar structures, as well as the advent of such adjuncts as penicillin has brought surgical treatment to a very safe level. Likewise, the refinement of segmental resection increases operability by conservation of useful lung. Operative mortality figures vary according to the circumstances involved but are given at as low as 1 per cent. In bilateral bronchiectasis the risk is increased not only because of multiple operations but because convalescence from the first resection must take place in face of persistent contralateral disease.

The results of 93 operations on 72 patients on the author's service which included multilobar as well as bilateral cases indicated a 9.7 per cent case mortality rate and a 7.5 per cent operative mortality rate (deaths directly attributable to operations).

The nonsurgical measures include postural drainage and bronchoscopy. The latter is important in ruling out concomitant or complicating intrabronchial lesions. Penicillin, although very beneficial in improving the patient's condition in preparation for surgery will not provide for permanency of results.

The more important complications of bronchiectasis such as putrid empyema, extensions of infection, metastatic brain abscess and hemorrhage are elaborated upon.

This paper was given as part of a symposium on bronchiectasis before the Massachusetts Medical Society, Boston, and is a concise but comprehensive review of the subject. **HERMAN T. LANGSTON, M.D.**

Cystic Disease of the Lungs. WILLIAM L. ROGERS.
West. J. Surg. 1948 56 157

The author reviews 6 cases of patients suffering from cystic disease of the lungs, all probably congenital in type. He presents certain criteria to assist in classifying the clinical cases.

Primary resection is advocated in most instances in which surgical intervention is indicated as the procedure of choice. However, the congenital type may present instances in which palliative decompression and drainage or multiple stage operations would be desirable. The paper is well illustrated. **STEPHEN A. ZIEMAN, M.D.**

Studies in Lung Abscess. Anaerobic (Fetid) Lung Abscess. Aerobic (Nonfetid) Lung Abscess.
R. C. BROCK. *Guy's Hosp. Rep.*, Lond. 1947 96 97 125

Brock discusses anaerobic and aerobic lung abscesses. He stresses the fact that the expectoration of pus, whether offensive or not, is important to the diagnosis of lung abscess. Lung abscess is regarded

as a clinicopathologic condition due to many different causes and processes. It is not an entity in itself.

Primary anaerobic (fetid) abscess is essentially an acute suppurative pneumonitis proceeding to a greater or lesser degree of gangrene and is characterized by a peculiar penetrating and exceedingly offensive smell. The smell arises from an anaerobic infection, often mixed which both causes the gangrene and flourishes on the dead tissue.

It is probable that the varied combination of spirochetes, fusiform bacilli, streptococci and other micro-organisms can cause anaerobic or fetid lung abscess in favorable circumstances and it may be that as yet unrecognized organisms, particularly anaerobic streptococci, are involved. Certainly actinomyces may be present and may be the only organism found in some cases of foul lung abscess.

The morbid anatomy considers acute fetid lung abscess (a) with formation of a slough and (b) without formation of a slough and chronic anaerobic pneumonitis complicated by or followed by new acute abscesses.

The clinical features show acute pulmonary gangrene and acute fetid lung abscess.

Secondary fetid abscess depends principally on an antecedent history of operation, dental sepsis or the like. An infected lung cyst may mimic a fetid lung abscess. Bronchiectasis, intrapulmonary or intrabronchial foreign body, bronchial carcinoma or adenoma and tuberculosis may introduce diagnostic difficulties. All these conditions may produce foul smelling sputum which contains anaerobes.

Treatment includes operative drainage but chemotherapy has achieved success without operation. The former should not be neglected because of the latter but should be done when resolution is slow.

Aerobic lung abscess in many cases is almost identical with acute fetid lung abscess except for the absence of the fetid smell. It is typically segmental in origin and most of what has been said about the pathology of fetid lung abscess applies to it also with the chief difference that a slough is not commonly found.

The fundamental process in the formation of a typical nonfetid abscess is generally a segmental pneumonitis due to bronchial embolism which proceeds to cavitation with the formation of a slough in very rare instances.

Primary aerobic lung abscess may be segmental or nonsegmental; the process may remain confined to one segment or skip to other segments of the lung. The clinical features differ little from those of the fetid type of abscess and the management of both types is similar. **STEPHEN A. ZIEMAN, M.D.**

The Rational Basis of Endobronchial Medical Treatment of Lung Abscess (Bases rationnelles du traitement médical endo-bronchique des abcès du poulmon). **MAX FOURSTIER and YVES LE BOUCHER.**
Presse méd. 1947 55 822

Ten cases of pulmonary abscess were treated either with penicillin alone or with a combination of peni-

illin and sulfonamide instilled endobronchially. The result was excellent in all cases.

Before the treatment is started bronchoscopy is done and the bacteriology of the pus is examined. If gram-positive organisms only are found, penicillin alone is used. If gram-negative bacteria are present as well, sulfonamide is used in addition to penicillin. A dose of 400,000 units of penicillin is instilled endobronchially through a Metras tube three times weekly after previous anesthetization of the area with 0.5 per cent pantocain solution. In cases of mixed infection 1 gm. of a water soluble sulfonamide is added to the instilled penicillin. In addition to the local treatment, penicillin alone or penicillin plus some sulfonamide is given intramuscularly. In the amount of 2,000,000 units of penicillin and 5 gm. of sulfonamide daily.

This treatment had to be continued for from 1 to 2 months until all signs and symptoms of the abscess had disappeared. WERNER M. SOLMITZ, M.D.

Mucoid (Gelatinous) Lung Cancer Characterized by Pronounced Bronchorrhoea (Cáncer gelatinoso del pulmón d forma broncorrheica). JUAN CARLOS DEL CASTILLO y ROMERO. *Rev. Soc. Med. P. R.* 1945, 40. *Cited per. dis. Intern.* 945 8 334.

This report concerns a man aged 62 who was seen in July 1945. In July 1944 he had suffered from a respiratory infection which was considered to be pneumonia on the right side. This was followed by a rather prolonged convalescence but he remained well thereafter until March, 1945, when the previous small amount of mucopurulent sputum began to increase in volume reaching 1500 c.c. on some days. The expectorated material was transparent, thick, and slightly frothy. He had lost 5 kgm. in weight over a 4 month period.

Studies after admission showed no fever, and no cardiovascular disease could be recognized. Urine and serologic examinations were negative.

X-ray examination revealed an opacity in the right lower chest conforming to the middle lobe distribution. Evidence of nodular infiltrates was noted in the left base and hilar region also. Bronchograms were not diagnostic, but showed no evidence of obstruction.

Sputum studies were not informative, being negative for acid-fast bacilli as well as for evidence of neoplasm.

Bronchoscopy revealed the source of sputum to be the right middle lobe but no cancer was seen.

Thoracentesis failed to yield fluid from the right chest. An aspiration biopsy from the right lung was performed and this material permitted the diagnosis of mucoid (gelatinous) carcinoma.

The patient was thereafter discharged, dying 4 months later. No autopsy is reported but the sputum had continued to be copious in amount and the changes as seen by means of roentgenography had been progressive.

Only 3 other such cases were found in the literature. These were published in 1841 and 1936. Both

of these cases were diagnosed by postmortem examination. The mechanism responsible for such copious outpouring of secretions is not clear.

IRVING T. LANGSTON, M.D.

Decortication of the Lung in the Treatment of Tuberculous Empyema. CONRAD R. LAX. *Arch. Surg.* 1945, 56: 7.

It is obvious that the procedure of decortication cannot be applied indiscriminately in all cases of tuberculous empyema. The parenchymal lesion must not be forgotten. The fluid and cortex may actually be beneficial for a while, because of their immobilizing and compressive effects. Sooner or later, however, one must decide whether the lung should be re-expanded or permanently collapsed. Decortication may be of value regardless of the decision.

If re-expansion of the lung is decided upon, decortication without thoracoplasty is the operation of choice. If intrinsic factors in the lung prevent its expansion, some alteration of the thoracic wall, obviously may be necessary. If permanent collapse is desired, extrapleural thoracoplasty may be supplemented with decortication to achieve final obliteration of the pleural space.

Pulmonary decortication was applied, with gratifying results, to 3 patients with effusions and unexpandable lungs which complicated treatment by pneumothorax. In 2 cases, the procedure was used as an adjunct in the closure of large wounds of the chest, following extensive thoracoplastic procedures. In the third case it was used as the primary attack on an unexpandable lung. SAMUEL KARY, M.D.

HEART AND PERICARDIUM

Syndromes of Aberrant Right Subclavian Artery with Patent Ductus Arteriosus. HENRY F. BIRAN and EDWARD D. D. NEUMACHER. *Am. J. Roent.* 1947 55 703.

The authors detected 15 cases of aberrant right subclavian artery by roentgen examination at the Infants and Children's Hospitals in Boston from September 1945 to August 1946. In 5 of the patients there was concomitant heart disease of a congenital nature (patent ductus arteriosus in 3 cases, the tetralogy of Fallot in 1 case and an anomaly of aortic structure but apparently involving an intracardiac shunt in 1 case). In 2 of the 5 cases the condition—a patent ductus arteriosus in one case and a tetralogy of Fallot in the other—was surgically verified.

The 5 cases of aberrant right subclavian artery associated with congenital anomalies of the great vessels at the base of the heart are reported in detail. In 4 cases the respective roentgenograms are presented for the purpose of illustration.

The aberrant right subclavian artery takes origin from the extreme left side of the aortic arch and passes obliquely upward and to the right behind the esophagus. In so doing it produces pressure on the posterior wall of the esophagus. By administering a swallow of barium mixture a typical oblique extrin-

filling defect appears in the barium column which is especially well visualized in the lateral view. An anomalous subclavian artery passing between the esophagus and trachea or anterior to the trachea is uncommon and has not been encountered in the authors series.

Of particular interest is the relatively high incidence of coexistent congenital heart diseases in the syndrome of aberrant right subclavian artery. The fact that a patent ductus arteriosus was observed in not less than 3 out of 15 patients suggests to the authors that the two entities may be related either by one constituting a direct causation for the other or by virtue of a common etiology and pathogenesis of both. The presence of certain virus infections in the first trimester of pregnancy may have in this respect a definite role. In one of the authors' cases the mother of the patient had German measles in the second month of pregnancy. There is accumulating evidence in the literature to the effect that German measles in early pregnancy is a common and potent factor in producing congenital heart disease, cataract, deafness and other anomalies.

The authors discuss also the embryologic background of the syndrome of aberrant right subclavian artery and associated congenital heart disease. In the transformation of the aortic arches during the second fetal month the fourth arch is normally absorbed just proximal to its junction with the dorsal aorta; the remainder of the arch becomes the normal right subclavian artery. In the anomaly, the proximal portion of the arch is absorbed instead; the portion of the arch which joined the dorsal aorta then constitutes the aberrant subclavian artery. In the presence of a coexistent tetralogy of Fallot it is reasonable to assume that both defects arose from the same disturbance of embryologic development. In the case of patent ductus arteriosus however the infectious theory appears more plausible; the defects being manifestations of a basic fetal abnormality induced by the virus agent.

In conclusion the authors stress the value of a routine barium swallow during roentgeoscopic examination of the heart and lungs.

T. LEUCOTIA, M.D.

ESOPHAGUS AND MEDIASTINUM

Present Day Concepts on the Treatment of Esophageal Perforations. FRANCIS L. LIDZERS, ARNOLD A. GROSSMAN and W. ALLEN DOWKELLY. *Ann. Otol. Rhinol.* 1947 56: 867.

Even before the advent of present chemotherapy there were conflicting schools of thought on the treatment of esophageal perforations. The problem is still undecided.

The interventionists recommend cervical mediastinotomy as soon as the diagnosis is made. The conservative group would rather wait and see if complications such as mediastinitis develop before they advise surgery if at all. Since the use of penicillin, the conservative method is no longer as great

a threat as it was before chemotherapy when 87 per cent of the cases terminated fatally.

Penicillin plays an important part in the treatment of this disease if we understand its limitations. It has by no means obviated the necessity of surgical intervention, especially when complications such as mediastinitis, pleural effusion, or empyema have occurred. Penicillin alone or with pleural aspirations, and the instillation of penicillin or streptomycin have been followed by cure in some cases.

Prior to the use of penicillin prophylactic cervicotomy done immediately, resulted in a 27 per cent death rate and the authors believe that chemotherapy associated with this procedure would be the most logical approach. Posterior mediastinotomy carried out at the same time or later has been recommended by some authors when the infection spreads to the posterior mediastinum below the fourth thoracic vertebra.

Both Churchill and Neuhof recommend early operation on patients with esophageal perforations without waiting for the infection to wall off or for roentgenographic evidence of mediastinitis to develop.

Since the use of penicillin the pendulum has swung to the side of the noninterventionists. If a diagnosis of esophageal perforation is made, the procedure should be as follows:

Instillation of 100,000 units of penicillin intramuscularly every 4 hours; nothing should be taken by mouth; intravenous feedings should be given; or a gastrostomy is done in long drawn-out cases; the patient is placed in Trendelenburg position to prevent secretions from running down the esophagus; 100 per cent oxygen is administered to combat cyanosis, dyspnea and restlessness; 50 mgm. of demerol is given every 4 hours as a sedative; anaerobic as well as aerobic bacterial investigations should be carried out; hydrogen peroxide sprays should be used to combat mouth organisms; iron and arsenic cacodylate (1 gr. daily) is given intravenously for 7 days; anti-gas gangrene and tetanus antitoxins and small and repeated blood transfusions should be administered; sulfadiazine (1 gm. every 4 hours) and streptomycin (0.25 every 4 hours intramuscularly) should be started as early as possible; thoracic surgeons keenly observant of such cases should be consulted.

When is surgical intervention indicated? The authors believe prophylactic cervicotomy should be performed in all cases of high esophageal perforation. Even though one adopts the conservative approach outlined, surgery still may be indicated in the later phases of this condition. Certain indicators repeated at frequent intervals will aid in the decision for surgical intervention. These are: (1) a history of known or suspected esophageal trauma; (2) roentgenographic evidence of air in the tissues; (3) clinical evidence of prevertebral or mediastinal emphysema; and (4) the course of the white blood count, the pulse and the temperature.

If these indicators show no progression of the disease expectant treatment can be continued. If

roentgenographic evidence and clinical findings plus some or all of the "indicators" show progression of the disease process. Immediate surgery should be carried out in the area indicated. If it is a high esophageal perforation alone then a cervicotomy must be performed at once. Following this, all "indicators" must be continued. If the chest film shows progression of the lesion chest aspiration and instillation of penicillin or streptomycin is indicated.

If in spite of this, the lesion progresses as evidenced in the volume of pleural effusion, determined by roentgenographic study then posterior mediastinotomy is the immediate and urgent treatment of choice.

Three cases are presented which illustrate the above outlined management. All 3 patients were treated with penicillin and all survived. One patient required major surgery in another pleural aspiration with local instillation of penicillin was necessary and in one patient conservative measures alone were enough.

The authors describe the treatment of esophageal perforations in 4 patients before the use of penicillin one of whom survived.

The early symptoms of esophageal perforation are (1) severe insistent pain at the site of perforation or between the shoulder blades, (2) dysphagia and expectoration of small quantities of blood and (3) dyspnea and restlessness.

ROBERT R. BUCKLOW M.D.

Surgical Treatment of Cancer of the Thoracic Esophagus (Traitement chirurgical du cancer de l'oesophage thoracique) P. SARRY and ALAIN MOUTIER. *J. chi. Par.* 94:7 63 595.

Surgical treatment of cancer of the esophagus is justified because of its great frequency, its serious consequences, its failure to respond to other methods of treatment, and its relatively long period of operability. The annual deaths due to cancer of the esophagus range from 1,000 in Argentina, 3,500 in England and more than 5,000 in the United States to 25,000 in Europe. In 1939, Balluret could collect only 54 cases of surgical cure, while today the number of cures exceeds 400. The operative mortality has dropped from 75 per cent in 1941 to from 15 to 30 per cent. Metastases develop late in esophageal cancer. The percentage of operability increases with the experience of the surgeon and today radical extirpation, even of tumors adhering to both pleurae, lungs, or a bronchus is advocated. A brief résumé of the historical aspects of surgery of esophageal cancer, of the surgical anatomy of the esophagus, and of the pathologic anatomy of thoracic esophageal cancer follows.

The frequently long period of latency between onset of the malignant process and appearance of clinical symptoms is emphasized. Frequently patients do not arrive for treatment until 4 or 6 months after the onset of symptoms. The tumor may remain operable for a long time after symptoms have appeared but in some instances it becomes inoperable within one

month of the onset of symptoms. The first symptom is dysphagia for solid foods. Other early symptoms include regurgitations, emaciation, epigastric distress following deglutition, retrosternal heaviness, or a burning sensation cough attacks of severe pain, which may suggest angina pectoris. The roentgenologic, esophagoscopy and bronchoscopy findings are described. Delay in surgical intervention may be due to loss of time in trying to relieve the dysphagia by antispasmodics or antisyphilitic therapy poor roentgenograms, or poor interpretation of esophagoscopy findings.

The contraindications to operation include first back pain, pain on percussion of the spinous apophyses, or fever and increased pulse rate indicating a large infected or ulcerated tumor. Neither weight loss nor debility are definite contraindications to operation. Absolute contraindications include pulmonary metastases, and metastases to the liver, peritoneum, or supraclavicular glands. Complicating abscess or fistula excludes the patient from surgical treatment, as well as cachexia persisting after 3 weeks of preliminary preparation. Also patients with cardiac lesions, bronchopulmonary lesions, and irreversible hepatic lesions are excluded. The physical condition of the patient counts more than actual age in determining operability as some good results have been reported in patients over 70 years of age. Reversible cardiac and bronchopulmonary lesions may of course respond to proper treatment and leave the patient amenable to operation. Preoperative preparation includes alimentation, rehydration, administration of vitamins and calcium, and injections of prothrombin.

Other preparative procedures include oropharyngeal disinfection, esophageal disinfection, respiratory exercises, and administration of sulfadiazine and penicillin aerosols. Preliminary gastrostomy is indicated only when the tumor is very stenotic, situated high up in the esophagus, and supra-aortic, so that only a Tork operation or cervical excision can be considered. Jejunostomy is indicated only in the presence of a rigid stenosis in a greatly debilitated patient who cannot be properly fed or in a patient whose cardiovascular system would not tolerate numerous intravenous perfusions following radical operation.

The classic technique for operation on cancer of the lower third of the thoracic esophagus is described, namely transpleural segmentary esophagectomy from the left side followed by low intrathoracic anastomosis. The advantages of Garlock's abdomino-thoracic approach are enumerated. Before closure of the abdomen he advises terminating the operation by instituting a jejunostomy so that the patient can be given nourishment immediately.

In operating on cancer of the middle third of the thoracic esophagus, 3 types of operation have to be considered namely (1) the ideal operation or resection followed by high left transpleural intrathoracic anastomosis (Garlock and Sweet) (2) right or left esophagectomy by Tork's technique and (3) resec-

tion followed by esophagogastric anastomosis from the right side necessitating a preliminary abdominal stage of gastrotomy. In the last type one may choose between three techniques, namely (1) the technique of Santy and Ballivet (2) the technique of Ivor Lewis, and (3) the technique of Herman Taylor. These are all described with the advantages and disadvantages of each. The three esophagogastric anastomotic procedures in use include anastomosis by invagination button anastomosis and suture anastomosis.

Unusual routes of approach include the cervical the upper thoracic, and cervicoabdominal tunneling.

For cancer of the lower third of the esophagus, the procedure of choice is block resection of the tumor and its glands by the left transthoracic route with immediate restoration of continuity by esophagogastric anastomosis. For a tumor extending toward the cardia, an abdominothoracic incision may be considered. For cancer of the middle esophagus the Torek operation should be rejected for esophagectomy followed by high anastomosis. For cancer of the upper thoracic esophagus i.e. supra-aortic cancer opinions still differ as to the best method of approach. There is no satisfactory solution to this problem, for it is quite impossible to restore continuity. For these, fortunately rare tumors an attempt at the cervical approach, the Torek intervention or tunneling may be made.

The best methods of combating postoperative complications of the early and later postoperative periods are discussed. Among the early measures are antishock therapy emergency evacuation for valvular pneumothorax, and bronchial aspiration for atelectasis. Infectious complications demand prompt application of sulfonamide therapy penicillin and pleurotomy for evacuation of the purulent collection. The site of infection is not always easily established.

Cardiovascular complications are common and often beyond therapeutic help. Chylothorax may result from injury to the thoracic duct and constitutes a serious complication as does likewise, diaphrag-

matic hernia through an inadequately sutured diaphragmatic incision. Rupture of the sutures may be partial causing purulent pleurisy which requires drainage and occasionally an emergency jejunostomy. Partial fistulization is curable. Total rupture of the sutures usually occurs earlier and is fatal as a rule. Finally there are the late complications of stenosis of the anastomosis which if not too pronounced may respond to endoscopic dilatation. Late diaphragmatic hernia may be discovered accidentally and does not always require treatment. In button anastomosis the danger of fulminating hemorrhage due to ulceration of the aorta when the button is left *in situ*, has to be considered. Generally speaking complications are more frequent following high anastomosis and, also cardiac complications are more numerous in these cases. Crushing of the phrenic nerve may prevent traction on the anastomosis and facilitate healing of the phrenicotomy. Division of the two pneumogastric nerves may interfere with peristalsis and cause pyloric spasm. Postoperative gastric disturbances are not uncommon but these are temporary symptoms. Sweet was obliged to do a secondary pyloroplasty in one case. Patients should be warned not to lie down after eating as in this position regurgitation may be annoying. In none of Sweet's cases did partial or total transposition of the stomach into the thorax cause the slightest respiratory or cardiac disturbance. Sweet's statistical results are reviewed; they show a higher mortality for higher anastomoses. Low resections appear to give about the same end results as high resections. From 30 to 40 per cent of the patients subjected to low resection survived from 2 to 3 years. In 1945 Garlock reported 24 survivals without recurrence for periods of from 10 years to 1 month after operation. These results obtained in the United States are proof of the possibilities of surgery of cancer of the esophagus when practiced by trained specialists and trained assistants in medicine bronchoscopy anesthesia and radiology.

EDITH SCHANCHIE MOORE.

SURGERY OF THE ABDOMEN

GASTROINTESTINAL TRACT

Technical Improvement in the Introduction of a Thread Guide and Its Recovery with an Electromagnet in Gastrostomy for Cicatricial Stenosis of the Esophagus (Accorgimento tecnico nell'introduzione del filo-guida e suo recupero con l'elettrocalamita nei gastrostomizzati per stenosi cicatriziale dell'esofago) ANGELO CUSATELLI *Chirurgia*, 1946, 318.

The author has developed a new method for passing a thread through a stenosed esophagus emerging through a gastrostomy for the purpose of passing Tucker sounds for dilatation. He uses small iron balls beginning with a diameter of 1.5 mm. and up. These are bored with a bore which has one half side larger than the other so that it will be possible to anchor the knot of the thread used. He prefers to use a small metal chain such as is used for neck medals, to silk thread. Since the type chains available to him are not magnetic he attaches the iron ball to the end. He recommends that the chain be as flexible as possible. The smallest usable type that he was able to obtain measured 0.7 mm. in width. Chains up to 2 or 3 mm. may be used, the important point being that they be flexible. The length used is 50 cm. although from 20 to 30 cm. would be sufficient. He states that the use of the metal ball would be superfluous if these chains could be made of steel or other magnetic metal. The electromagnet is made of soft iron in the shape of a baton upon which is woven an insulated copper wire. This is mounted on an ebony handle and is furnished with an introducer. It is made in two sizes—5 mm. in width and 12 cm. in length and 5 mm. in width and 25 cm. in length.

The chain and ball are introduced through the nose and the length necessary to reach the external opening at the gastrostomy is measured so as to avoid its going on beyond the pylorus. The position is controlled with roentgenographic study. If there is difficulty in passage, small sips of water will usually help. When the ball has reached the stomach the patient is placed in the supine position so as to allow it to rest on the posterior wall. The electromagnet is then introduced under roentgenographic control and when it is near the ball the current is turned on. The ball is then easily extracted. Direct current is necessary for the magnet and the author uses batteries that are used with endoscopic instruments. The small magnet requires 4 volts, the larger 6 volts.

The roentgenographic control is recommended at the beginning but after the opening is somewhat enlarged the procedure can be easily carried on without its aid.

This procedure is recommended for persons who object to the constant wearing of the usual silk thread guide and the chain and ball are introduced at each dilatation. LUCIAN J. FROMMELT, M.D.

Surgical Treatment of Cardiospasm. EARLE B. HAY *Ann. Surg.* 945, 127-34.

Instrumental dilatation of the esophagogastric junction may result in temporary symptomatic improvement in cardiospasm. This form of therapy may not be successful or may be contraindicated when there is marked tortuosity of the esophagus.

Numerous operative procedures have been used in the treatment of this condition with variable results. Techniques designed to enlarge the esophagogastric stoma have given the best results. The functional improvement is usually better than the change in x-ray appearance of the esophagus. The transabdominal approach is favored by most surgeons who believe that it is associated with less risk.

The author describes the technique employed and the results following transpleural cardioplasties in 17 patients. In none of these patients had the condition been significantly improved by dilatations. Symptomatic improvement and a marked reduction in size of the esophagus was observed postoperatively.

All cardioplasties were performed through a transpleural approach. The stoma was made large enough to allow reduction in size as the caliber of the esophagus decreased. The first three cardioplasties were performed in a manner similar to a Finney pyloroplasty and the others were carried out in a manner similar to a Hebecke-Blikkies pyloroplasty. The latter procedure was easier and more satisfactory.

The lower esophagus is mobilized and carefully inspected before the diaphragmatic hiatus is incised radially. The author stresses the importance of inspecting and incising any limiting bands in the diaphragmaticoesophageal ligament. This ligament appeared responsible for the esophageal obstruction in 5 patients. Detailed descriptions of several cases in which this ligament caused obstruction are given. The site of the ligament can best be inspected by enlarging the diaphragmatic hiatus, incising the peritoneum, and retracting the cardia of the stomach into the thorax. The esophagus and stomach are occluded by umbilical tapes. A longitudinal 4 inch incision is made through the esophagogastric junction. This opening is closed transversely in two layers. Approximately 100,000 units of penicillin are injected about the stoma. The stomach and new stoma are replaced in the abdomen and the diaphragm closed about the esophagus at a higher level. The chest is closed without drainage.

The only postoperative complications have been transient collections of serum in the pleural space of 4 patients. Hourly feedings of milk are begun as soon as the patient recovers from anesthesia. The Wangenstein suction pump is clamped intermittently for 3 days. The usual postoperative gastric diet is then provided.

All these patients were convinced of the greater relief afforded by operation as compared to instru-

mentation. Many patients exist for years with partial relief afforded by instrumentation without realizing the more complete and permanent benefit from this operation. ROBERT R. BIGELOW M.D.

A Statistical Study of 112 Cases of Benign Gastric Ulceration MAURICE FELDMAN *Am J M Sc.*, 1948, 215 13.

In a detailed study of a series of 7,300 ambulatory patients presenting varying digestive disturbances peptic ulceration was found in 1,266 cases. Of these 1,154 (86.7%) were duodenal lesions and 112 (17.3%) were gastric. An analysis of the duodenal ulcers having previously been reported the author here concerns himself with the statistics of benign gastric ulcer in relation to (1) incidence (2) site (3) age and sex, (4) duration of symptoms (5) symptoms and signs, and (6) recurrences.

The corpus and cardia were found to be involved in 74 cases and in 38 patients the pylorus was the site of the ulceration. By comparing cases seen during the period from 1937 to 1941 with those examined in the period from 1941 to 1946 the incidence of gastric ulceration was found to have increased from 0.8 to 1.2 per cent during the war years. There was a slight increase in the incidence of gastric ulcer in females during the years of war and gastric ulcers of short duration (or acute ulcers) were generally more common during this period. Recurrences were found to be less frequent in gastric than in duodenal ulcers. Pyloric ulceration was found in 38 of the 112 cases save for a greater prevalence of obstruction, the behavior of the pyloric lesions was like that of the gastric type. WAYNE F. CAMERON M.D.

Clinical and Pathologic Studies of Papillary Mucous Tumors of the Stomach; Gastric Papillomas (Beitrag zur Klinik und Pathologie der papillären Schleimhautgeschwulste des Magens (Magenpapillome)) A. IKLE. *Helvet. chir. acta*, 1947 14 435.

Seven cases of papillary fibroepithelial gastric tumors, 3 in men and 4 in women are reported by the author. The lesion usually does not become manifest before the fifth decade and affects both sexes equally. The role of hereditary factors could not be established in the author's material.

Digestive disturbances accompanying the lesion do not allow its differentiation from an ulcer or a cancer. A tumor is palpable only in rare instances. Secondary anemia is often found and occult blood is nearly always demonstrable in the feces while hematemesis occurs with lesser frequency. Hypacidity or anacidity is present in practically every case. Roentgenologically filling defects without induration of the adjoining portions of the stomach wall and without interference with the peristalsis allow differentiation of the condition from a cancer. A spongy foamy pattern created by the papillary formation may sometimes be demonstrated in the roentgenograms.

Palpation of the exposed stomach may fail to reveal the tumor and therefore if the roentgenologic

findings are positive, an incision through the stomach wall is indicated. A simultaneous occurrence of a papilloma and a peptic ulcer was observed by the author in one case. A combination of a papilloma and a cancer has also been reported.

In view of the fact that papilloma of the stomach should be considered a precancerous lesion an extensive gastric resection is indicated.

Pathologically the structure of papillomas of the stomach resembles that of similar lesions in the large intestines and in the urinary bladder.

JOSEPH K. NARAT M.D.

The Terminolateral Anticolic Gastrojejunostomy in Gastric Resection (La gastro-diguno-stomia termino-laterale antecolica nella resezione gastrica) NINO DELLA MANO *Boll. Istit. Soc. piemontese chir.* 1946 16 431.

The author a student of Donati believes that antecolic gastroenterostomy should have a more widespread application than it now has. He feels however that the type of operation performed should depend upon the findings at the operating table.

Certainly in a patient with a wide transverse mesocolon with extensive zones showing no blood vessels one should not do an antecolic gastrojejunostomy. However in the presence of a retracted mesocolon or one not well developed or one with extensive blood vessels in which difficulties would be encountered in attempting to accomplish an opening wide enough one may constrict the blood vessels and thereby place the vitality of the transverse mesocolon in danger. In these cases the author suggests giving preference to the antecolic anastomosis without using the deprecated enteroenterostomy of Braun.

Gastric resection until recently was considered a grave intervention not without dangers for which a special technique was recognized. It was considered in the domain of an elected few and a high mortality was expected. At present however, with the perfection obtained in the technique with the adoption of local anesthesia, with the preparation of the patient by means of efficacious therapeutic measures (chief of which is blood transfusion) and with the measures at hand to combat complications it has become the common practice of any surgeon. The mortality has markedly decreased because of the improvements in both technique and therapy.

The principles of gastric surgery as expounded by Donati and followed by his students are to make the intervention as simple as possible to make use of any contribution which would make the execution of the operative act less difficult to reduce the immediate dangers and eliminate the conditions which may favor disturbance in function in the future.

LUCIAN J. FRODOTTI M.D.

Lipomas of the Large and Small Intestine. ROBERT J. TENNER. *J. Lancet* 1948 68 12.

The author felt that a careful clinical and pathological study of submucous lipomas would be of

value because they so closely resemble malignant neoplasms of the bowel in clinical features.

The lipoma is the second most common benign tumor of the intestinal tract. The adenomatous polyp is first and the fibroma third. Submucous lipomas are more frequent than subserous ones and are also more apt to produce symptoms. Intussusception is a common and important complication of submucous lipomas.

Twelve cases of submucous and intramucosal lipomas of the large and small intestine are presented.

Pain was reported to be the most common symptom. It lasted 9 years in one case and only 2 months in another. Vomiting and constipation were present in 6 of the 12 cases. Diarrhea was not a common symptom. Definite weight loss of as much as 25 pounds was frequent. A mass palpable on physical examination was present in 8 cases; the tumor was demonstrated by the roentgenologist in every case. Ulceration of the mucosa covering the tumor was found microscopically in 12 cases. Occult blood in the stool was found in only 5 cases.

Seven of the lipomas were found in the colon and 3 in the cecum and 1 each was found in the jejunum and ileum. The average age of the 12 patients was 53 years.

Six of the lipomas were found in the submucosa, 3 had their origin between the inner circular and the outer longitudinal muscles of the intestinal wall, and 3 had their origin within the inner circular muscle. The author classifies these as submucous, intramucosal, intermuscular and subserous.

Treatment of the tumors is surgical either local excision with direct closure or anastomosis if the lesion is not too extensive. A resection of the segment of bowel containing the tumor is frequently done.

W. FORTER MONTGOMERY M.D.

Obstructive Lesions of the Small Intestine and Sigmoid Due to Irradiation. JAMES G. SPACKMAN. *Ann. Surg.* 948, 27.

The author presents a series of 5 case reports to emphasize the late clinical picture of obstruction due to irradiation. In each case the irradiation was for pelvic carcinoma. Patients who develop low sigmoid and rectosigmoid lesions soon after irradiation complain of cramplike abdominal pains associated with frequent small liquid stools containing mucus and blood. When the acute hyperemia and mucosal edema phase recedes and is replaced by cicatricial contraction, the physical signs of low sigmoid obstruction appear.

Since the terminal ileum is frequently in the pelvis signs of small intestinal obstruction may often appear earlier than those of obstruction of the low sigmoid.

It is important to remember that any patient who has received irradiation and later develops bowel symptoms (abdominal pain, nausea, vomiting and change of bowel habits) does not necessarily have a recurrence of the primary neoplasm. The stenosing obstructing lesion may be a late result of irradiation

amenable to proper surgery and with a more favorable prognosis. Abdominal exploration after appropriate study is indicated in all cases.

If the sigmoid lesion is acute and not due to scarring, a proximal colostomy may lead to regression by decreasing the edema and infection and eventually restoring the normal lumen. In dealing with all these lesions, the author believes a preliminary proximal diverting colostomy is indicated.

ROBERT R. BICKLOW M.D.

Neurinoma of the Small Bowel with Secondary Volvulus of the Ileocecum (Neurinoma del tomo o volvulo secundario del ileo-ceco-ascendente). LEONIDA MAMEOCCHE. *Chirurgia*, 946 11: 32.

The author reports a personally observed case in which the patient presented a picture of recurring attacks of abdominal pain accompanied by mechanical ileus. Gynecological examination revealed a tender mass about the size of a fist in the right pelvic cavity which was displacing the uterus anteriorly. The patient was considered to have an ovarian cyst which had twisted on its pedicle. She also was found to have rheumatic mitral valve disease which had been present since early youth. She was now 65 years of age.

At operation she was found to have a volvulus affecting the distal ileum, cecum and ascending colon. There were 360 degrees of rotation in a clockwise direction. The involved bowel was distended and presented multiple punctate hemorrhages. A large loop of jejunum was also present, extending from front to behind the volvulus. This loop was stretched and attached superiorly at its mesenteric origin. It was stretched into the pelvic cavity by the weight of a tumor mass about the size of a large fist. It was white in color, granular and of rubbery hard consistency. The origin was from the convex margin of the bowel. About 15 cm. of jejunum were resected and an end-to-end anastomosis was performed. The volvulus was then easily reduced. A lymph gland was also removed for biopsy.

The postoperative course was stormy because of cardiac decompensation with improvement after the fifth day. Ten months later the patient had no symptoms. The microscopic diagnosis was neurinoma.

The literature is reviewed and some of the interesting points are brought out. Neurinoma or schwannoma, a tumor found frequently in the central and peripheral nervous system, has been found especially recently in various organs. It can be found in any organ which contains myelinated or amyelinated fibers furnished with a sheath of Schwann. Two morphologic types are described, the fascicular and the reticular. The digestive system is the most frequent site of a neurinoma outside of the nervous system.

The clinical picture may be that of intestinal hemorrhage, palpable abdominal tumor, intestinal obstruction, or inflammation simulating acute appendicitis with peritonitis.

The histological diagnosis is at times difficult and may resemble small spindle cell sarcoma. Two cases of neurinoma have been reported to have become malignant. The author however is inclined to believe that neurinomas are benign and that those which have been reported as having undergone malignant change were not neurinomas to begin with. Altogether 13 cases have been reported in the literature.

There are excellent illustrations depicting the anatomy as found at operation and also the histology of the tumor mass. LUCIAN J. FRONZUTI, M.D.

Delayed Results of the Surgical Treatment of Duodenal and Gastric Ulcer (Resultados alejados del tratamiento quirúrgico de la úlcera gástrica y duodenal) RONALDO E. PASMAN *Rev. As. Méd. Argent.* 1947 61: 883

Pasman reports the surgical results obtained in a series of 182 gastrectomies done in the period from 1940 to 1946, 36 were performed for gastric ulcer, 146 for duodenal ulcer and 11 for jejunal ulcer. The overall mortality was 4.6 per cent.

The author recommends subtotal gastrectomy as the elective surgical treatment for peptic ulcer and believes that gastroenterostomies are indicated only in exceptional circumstances. Extensive resection of the stomach is advised to avoid the formation of jejunal ulcers which did not occur in any case of this series. The author compared these results with those obtained in the period from 1929 to 1940—61 gastroenterostomies with a mortality of 20 per cent and 218 gastric resections with a mortality of 14 per cent. WILLIAM E. RICKETTS, M.D.

Delayed Results of the Surgical Treatment of Duodenal and Gastric Ulcer (Resultados alejados del tratamiento quirúrgico de la úlcera gástrica y duodenal) FEDERICO E. CHRISTMAN *Rev. As. Méd. Argent.*, 1947 61: 888.

Christman reports the overall results obtained in 673 patients subjected to gastric operations. One hundred ninety four had gastric ulcers, 331 had duodenal ulcers, 169 had juxtapyloric ulcers and 5 had jejunal ulcers. There were also 47 perforated ulcers. The operations done were 120 gastroenterostomies and 394 gastrectomies, the total mortality being 5.6.

The author emphasizes the importance of preoperative and postoperative care of patients to reduce the incidence of mortality after resection of the stomach. The treatment of peptic ulceration is considered primarily a medical problem and surgery is advisable only when there has been failure of the medical treatment. The main indication for surgery is perforation of an ulcer.

WILLIAM E. RICKETTS, M.D.

Obstruction Due to Volvulus of the Colon R. K. GILCHRIST *Arch. Surg.*, 1948 56: 79

The author reports his experience with 5 cases of acute obstruction. In 4 of the patients the condition

was caused by volvulus of the sigmoid and in 1 patient by volvulus of the cecum.

In older patients with acute obstruction caused by volvulus of the sigmoid there is usually a history of repeated attacks of constipation or of partial obstruction. Such history is absent in the younger patient. The patient usually does not appear as sick as one might expect with carcinoma. Abdominal distention may be pronounced but vomiting occurs late. The red blood cell count and the hemoglobin value are usually not much below normal. Pain over the dilated intestinal loop is particularly marked where the twist puts a pull or pressure on the root of the mesentery. This pain is very severe if there is much interference with the circulation.

In sigmoidal volvulus decompression may be obtained by placing the patient in the knee-chest position and doing a sigmoidoscopy. In very sick patients cecostomy is indicated to be followed by a resection of the sigmoid at a later time. Obstruction due to volvulus is not relieved by intestinal Miller Abbott intubation and suction.

Resection is the treatment of choice. When an interval operation can be performed resection and end-to-end anastomosis are feasible. Lateral anastomosis will give good results in some patients. Untwisting and fixation are unsatisfactory.

Volvulus of the cecum depends on the failure of fixation of the colon. Cecal obstruction is associated with early obstruction of the small bowel, vomiting occurs earlier, dehydration ensues, and the patient appears more sick than the patient with sigmoidal volvulus. Intestinal intubation with suction is useless. Early operation is indicated. Untwisting and fixation to the bottom of the pelvis and left pelvic wall is the safest method of treatment. If this procedure fails to give permanent relief, resection of the redundant bowel with lateral anastomosis is indicated at a second operation. If the bowel is gangrenous resection with transverse colon ileostomy is indicated. ROBERT TURELL, M.D.

An Evaluation of the Clinical Management of Chronic Ulcerative Colitis. EVERETT D. KIEFER. *Gastroenterology* 1948 10: 16

Chronic ulcerative colitis is discussed in relation to the three main objectives in management: (1) the control of symptoms and support of the patient's general condition; (2) the cure or arrest of the colitis; (3) the success or failure of the treatment in preventing chronic invalidism.

The first phase is stressed because 'specific therapy' has not been generally successful and therefore palliation and supportive measures have been important until the patient's natural resistance could bring about a remission or an arrest of the disease. Diarrhea is managed by a low residue diet which does not stimulate intestinal motility, and by kaolin or bismuth to slow motility and solidify the stools. Deodorized tincture of opium is of value in acute flare-ups of diarrhea and papaverine in dosages up to 6 gr. per day is used to control cramps.

and diarrhea. Bed rest and sedation are important measures. In acute emergencies complete starvation with intravenous alimentation is maintained for several days. Malnutrition is treated chiefly by a liberal diet, with proteins stressed in cases in which hypoproteïnemia exists. Protein hydrolysates and intravenous amino acids are both of use in protein deficiency. Supplemental vitamins, particularly vitamins C and B complex, are important because of impaired absorption in ulcerative colitis. Electrolyte loss is corrected by intravenous saline solution plus glucose and when hypochloremia is marked an additional 10 gm. of sodium chloride per liter of intravenous infusion is used. Blood protein depletion and anemia are corrected by the liberal use of transfusions of whole blood and plasma. Iron in the form of ferrous sulfate or ferrous gluconate is used for mild anemia. Foci of infection or any other defect in the patient's general health receives specific attention. The emotional problems of the patient and his adjustment to the disease receive cure.

In analyzing the effect of the "specific therapy" upon the disease the cases were divided into (1) the febrile nontoxic conditions of comparatively short duration which were usually relieved by nonspecific management (2) the febrile, toxic manifestations of ulcerative colitis, usually with complete involvement of the colon and (3) those cases in which there was extensive irreversible organic damage of the colon and rectum which made return to normal function practically impossible.

All patients who received "specific therapy" also received palliative supportive therapy. The effectiveness of the "specific therapy" was estimated by reviewing the hospital records of the patients and checking the effect of the treatment upon the diarrhea and the fever. The cases were first carried for a period of several days of nonspecific treatment to establish a base line.

Many specific agents were tried. The list included the diplostreptococcus vaccine of Bergen sulfanilamide neopronthil, sulfadiazine sulfasquandine sulfasuxidine sulfathalidine penicillin, streptomycin fever therapy with intravenous typhoid vaccine antiamoebic therapy and antiallergic treatment. In almost all cases the results were poor or equivocal. Of the sulfonamides, sulfasquandine gave the best response, but only 7 of 26 patients were definitely benefited by the treatment. Penicillin and sulfasuxidine were of greatest value as adjuncts to preoperative and postoperative management, and in controlling complications of the disease such as abscess or peritonitis. Antiallergic treatment was of questionable value but perhaps diets eliminating milk, wheat, eggs and fresh fruit are of some value.

A tabulation of the 537 cases in which the patients were treated medically and followed up for 5 years or more showed that the results were satisfactory in 46 per cent and unsatisfactory in 54 per cent of the cases. Medical management was successful in about two-thirds of the patients with the milder forms of the disease only one-third of the patients

with more severe forms of the disease obtained satisfactory results. Of 400 patients treated medically 99 eventually had to come to operation.

FREDERICK C. HORNEL, M.D.

The Surgical Treatment of Ulcerative Colitis. ROSE AND D. CATTILL. *Gastroenterology* 64:8, 10: 62.

Surgical treatment of ulcerative colitis accomplishes two things. First, it places the colon and rectum at complete rest by defunctionalizing them by diversion of the fecal stream. Second, it permits removal of the affected bowel when the infectious process cannot be arrested by medical means.

Medical management includes physical rest, a low residue nonirritating diet, and the use of antispasmodics to decrease intestinal contraction but none of these measures are as effective as ileostomy. Ileostomy can also be used for treatment of the defunctionalized colon if it is considered desirable since it permits satisfactory mechanical cleansing of the bowel, the use of antiseptics or antibiotics, as well as bland solutions or emulsions.

Over a period of 20 years at the Labey Clinic, 26 per cent of the patients under treatment for ulcerative colitis have been operated upon. A review of the fatal cases following operation demonstrates at once that two-thirds of the fatalities occur when operation is done as an emergency. The mortality will probably always be high no matter at what time in the period of observation of the acute fulminating case operation is decided upon, but it will be much lower if ileostomy is done within 2 or 3 days, during which time supportive measures, including the use of antibiotics and blood transfusions, are employed. There will also be a higher rate of complete remission of symptoms. This will permit closure of the ileostomy in 10 per cent or more of the cases.

The importance of malignant degeneration in patients having ulcerative colitis for many years has not been sufficiently appreciated. 7 per cent of all patients who had been operated upon developed it. Furthermore, of the group of patients who had had ulcerative colitis for 9 years or more, 1 in 3 had carcinoma—an additional reason for performing colectomy in long-standing cases, particularly in those in which the discharge of blood continues. Once the malignancy develops it will usually be found to be inoperable since early dissemination is frequently encountered.

One would not be justified in submitting patients to operation unless their condition subsequent to operation would be consistent with a reasonable activity both from the economic and the social point of view. In the early experience with ileostomy it must be admitted that its management was unsatisfactory. At the present time, however, the management of an ileostomy is no longer a difficult problem. The patients can be fitted with a temporary bag, such as the Travellor which will fit any ileostomy and it can be applied within 7 to 10 days of operation. Within a period of 6 to 8 weeks a permanent bag of the Rutzen type can be utilized. This bag is cemented to

the skin and prevents any ileal discharge from coming in contact with the abdominal wall which avoids all possible irritation. Furthermore, it can be worn equally well at night so that there is no soiling of the bed clothes.

Unfair comparisons of the mortalities following the medical and the surgical treatment of ulcerative colitis are frequently made. It should be appreciated that the selected group of patients submitted to surgery represents only the most serious and complicated cases—the medical failures. All physicians interested in this subject are willing to accept the fact that all patients with ulcerative colitis should be treated medically as long as they can be cared for satisfactorily. Approximately a fourth or less of the total cases are submitted to operation. While the mortality over a 20 year period was 22 per cent, during the last 3 years it has dropped to 4 per cent because of the experience gained in the earlier years.

STEPHEN A. ZIEMAN M.D.

The Arterial Supply of the Distal Colon Pertinent to Abdominoperineal Proctosigmoidectomy with Preservation of the Sphincter Mechanism.
HARRY E. BACON and CALVIN H. SMITH. *Ann. Surg.* 1948, 127, 38

The arterial pattern of the colon has been a fundamental factor in determining the types of surgical procedures which can be successfully applied to that segment of the intestinal tract. In the surgery of the sigmoid and rectum the configuration of the arteries supplying these areas has been a particularly important consideration.

In the development of the present technique of abdominoperineal proctosigmoidectomy with preservation of the sphincter mechanism extensive precautions have been taken to insure the viability of that portion of the colon which is brought down to the perineum. The feasibility of the operation was first established in animals. In 71 cadavers the vascular supply of the colon and rectum was studied and the mobilization and transplantation of the viable bowel to the anus were proved to be practicable. In every operative case the pattern of the inferior mesenteric artery and its branches was noted by transillumination before any vessels were ligated.

The arterial supply to the segment of the bowel to be transplanted to the anus was observed by the same means after ligation of the inferior mesenteric artery. The distal point of viability was marked with a black silk suture, which facilitated its identification during the perineal phase of the operation. The distal point of viability was brought 7 cm. out side the anus. Viability was further assured by incising small vessels in the mesentery of the bowel and noting free bleeding.

This experience with abdominoperineal proctosigmoidectomy with preservation of the sphincter mechanism in 264 cases (from a total of 407 colon resections) may be considered to have been a method of study of the arteries to the sigmoid and upper rectum.

The configuration of the inferior mesenteric artery and its branches must be determined in each case by transillumination of the mesentery. Only in this way can the proper point for ligation be established consistently. Thus on the basis of studies of cases at operation the authors have confirmed the recommendation of both Sudeck and Hartmann that it is wise to observe in each patient the arterial pattern of the inferior mesenteric artery and its branches.

In the technique of abdominoperineal sigmoidectomy with preservation of the sphincters the last sigmoidal artery may be disregarded. The superior hemorrhoidal artery cannot be ligated below the origin of this vessel and allow sufficient mobility of the bowel to permit its being brought down to the anus without tension. As a corollary it is impossible in performing this operation to clamp the superior hemorrhoidal artery at the critical point of Sudeck.

The authors have been able to segregate those cases in which ligation may be made safely between the lowest two sigmoidal arteries from those in which ligation must be performed higher than the second lowest sigmoidal artery to assure viability, by the simple precautions previously described. Chief among these measures has been transillumination of the mesentery before and after ligation of the inferior mesenteric artery.

In an end-to-end anastomosis following resection of the sigmoid viability of each end must be assured.

In performing abdominoperineal proctosigmoidectomy with preservation of the sphincter mechanism the critical point of Sudeck need hardly be considered. Ligation of the inferior mesenteric artery must be performed above the lowest sigmoidal artery at least to permit the mobility of the colon necessary to bring it to the anus. Furthermore, the inferior mesenteric artery may be deliberately ligated much more proximally in cases in which more of the upward lymphatic pathway is to be removed or cases in which one is not completely satisfied with the competency of the circulation to that portion of the bowel to be brought to the anus. In the average case the most convenient place to ligate the inferior mesenteric artery is immediately below the first sigmoidal branch which can be recognized by the large anastomosis it forms with the left colic artery.

In selected cases of polyposis ulcerative colitis, diverticulitis, and lymphopathia venereum the rectum, sigmoid, descending colon, splenic flexure and a portion of the transverse colon have been excised. In these cases all branches of the inferior mesenteric artery have been ligated and the stump of the transverse colon has been brought down to the perineum. Viability has been maintained by the middle colic artery.

CHARLES BARON M.D.

Hauastrocecal Invagination (Invaginazione antra cecale) RICCARDO SCENDRATZ. *Boll. Mem. Soc. piemontese chir.* 1946 16 463.

The author reports a case of hauastrocecal invagination which was diagnosed at the operating table but the preoperative diagnosis was acute appendicitis.

tis. The cecum was near the hepatic angle and the lateral and anterior walls were invaginated into the lumen of the cecum. The base of the appendix was involved in the intussusception. The ileocecal valve was not invaginated. A loop of small bowel about 30 cm. from the valve was invaginated into the cavity formed by the invagination of the anterolateral wall of the cecum. The ileal loop was in good condition and contained hemorrhagic fluid. The wall of the cecum was markedly edematous.

The invagination was easily reduced and cecal plication extending into the ascending colon was performed. The appendix was removed and the lateral wall of the cecum was fixed to the lateral abdominal wall. The postoperative course was good.

The literature is reviewed and the conclusion was reached that there is no definite clinical picture and the etiology is obscure. Most cases are diagnosed as acute appendicitis. The author maintains, however, along with Russo, Sorensen and Angels, that if the condition is kept in mind there are sufficient signs to enable one to make a diagnosis. The important points are:

The patient usually has had abdominal cramps many times the pain is not continuous there may be diarrhea with blood especially with cecocolic invagination, occlusive phenomena, meteorism, and vomiting. There is tenderness and muscle spasm in the region of the appendix during the attacks of pain. In between the attacks the abdomen is relaxed and at this time a small mass about the size of an egg with indistinct margins can be palpated. Most important is the fact that palpation of the mass frequently causes attacks of pain. While roentgenographic study with a barium enema is of value, it is considered too dangerous a procedure to use except in recent mild cases. Previous experience is considered of great help in making a diagnosis. To prove this point a second case is reported in which the diagnosis was made preoperatively. The diagnosis was confirmed by roentgenographic studies and also at operation. LUCIAN J. FROMMELT, M.D.

An Acute Condition of the Abdomen following Gangrene of the Wall of the Cecum (Addome acuto da gangrena parietale del ceco) ERON BERENDSEN *Chirurgia*, 1946, 385.

The author presents a case of gangrene of the cecum caused by carcinoma of the colon at the hepatic flexure. The patient had had a heavy sensation in the right iliac fossa for over a year with slight change in bowel habit manifested by poorly formed stool from time to time. He then developed a sudden attack of pain in the right iliac fossa which lasted for one-half hour. About 9 days later he had a second attack which lasted for 15 hours. Again 3 days later he developed a third attack. This time, however the pain persisted and was accompanied by vomiting.

The patient was hospitalized, a diagnosis of acute appendicitis was made and operation was performed. At operation a gangrenous area in the cecum on the anterior wall was noted it measured 4 by 3 cm. The

appendix was free and hyperemic. The cecum was sutured to the anterior abdominal wall the sutures being placed beyond the gangrenous area. The abdominal wall was closed with through-and-through sutures of heavy silk. On the second day the gangrenous area was opened and this was followed by abundant fecal drainage. After 22 days the abdomen was explored, when a mass in the right hepatic flexure was found, about the size of a mandarin with no evidence of metastasis. An ileotransverse colostomy was performed. On the third day the patient had a natural bowel movement. However, on the sixth day he developed phlebitis in the right lower extremity with elevated temperature. This delayed the third operation which was performed after 35 days. At this time a hemicolectomy was performed and patient became ambulant after 16 days.

The pathologic report showed the mass to be an ulcerative infiltrating carcinoma. Two nodes removed in the right angular region showed a simple hyperplastic reaction.

The literature is reviewed and the first similar case was reported by Heschl in 1880. Seventy cases were reported up to 1945. Two theories prevail as to etiology one is that pressure caused by a stenosing lesion causes a rupture and the other is that pressure causes venous stasis and intraparietal hemorrhage, followed by focal necrosis and subsequent infection leading to perforation. The author states that this case represents the fifth case reported with successful outcome. LUCIAN J. FROMMELT, M.D.

Rectal Polyps: Diagnosis, 5 Year Follow Up, and Relation to Carcinoma of the Rectum. JAMES R. COLVERT and CHARLES H. BROWN *Am. J. M. Sc.*, 1945, 5:24.

The potential malignancy of benign rectal polyps is a controversial subject. One author found a variation of from 5 to 85 per cent in the malignancy index of rectal polyps, and other writers have contended that the probability of cancer increases with the number of polyps present, approaching 100 per cent in disseminated polyposis. Colvert and Brown observed 235 cases of rectal polyps at the Henry Ford Hospital, Detroit, with a follow-up over a 5 year period of 174 patients. In the present series, rectal polyps were found in 23 per cent of routine proctoscopic examinations, nearly three-fourths of these benign lesions were found in patients from 30 to 60 years of age, and 65 per cent of the patients were males.

In nearly all of the cases there were no symptoms due to the polyps, the large majority of patients being examined because of irritable colon distress. Proctoscopy was done in 21 cases because of rectal bleeding (not all of which was due to the polyp) and 9 patients were seen because of rectal discomfort which the authors believe, was not due to the polyp.

From the foregoing it is concluded that rectal polyps are essentially asymptomatic, and cannot be diagnosed except by proctoscopy. Barium enemas and, most particularly the double contrast

method of roentgenographic study, was found to be of importance in revealing colon polyps in addition to those found at proctoscopy.

When neoplastic changes were detected the malignancy was of low grade—frequently of grade 1 and never more than of grade 2.

Of the total number of 235 patients 176 had their polyps removed. Multiple polyps were demonstrated in 32 patients and 14 patients had recurrent polyps.

It was found that whereas size and shape were in no way related to the presence of malignancy ulceration was seen to occur seven times more frequently in malignant than in benign polyps. The total incidence of malignancy for a 5 year period in the patients whose lesions were removed was 8.4 per cent. Cancer was found to be present in 5.9 per cent of initial biopsies and 2.5 per cent of the patients subsequently developed carcinoma of the rectum. In the group of patients who did not have their polyps removed, the incidence of cancer of the rectum was 6.9 per cent. This last suggests to the authors that malignancy in rectal polyps either develops early or is present from the start and that there is no evidence that benign adenomas become malignant with the passage of time.

The authors advocate the removal of all rectal polyps, since the determination as to malignancy can not be otherwise made. The prompt removal of the majority of polyps in this series resulted in a 5 year cure without any major surgery in 13 of 14 patients with malignancy.

WAYNE F. CAMERON, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Biliary Tract Surgery in Passavant Memorial Hospital. THOMAS C. DOUGLASS and BENJAMIN F. LOUNSBURY. *Q. Bull. Northwest Univ. M. School* 1948 22 21.

Seven hundred and twenty four operations on the biliary tract are reported among which were 540 cholecystectomies and 32 cholecystostomies. The mortality for all biliary tract operations was 5 per cent. In the cases of cholecystectomy the mortality was 1.5 per cent, and in the cases of cholecystostomy the mortality was 18.7 per cent.

Carcinoma of the gall bladder or bile ducts was present in 1.9 per cent of all the operative cases.

The omission of drainage did not seem to affect the frequency of complications, nor did it contribute to the mortality. Of the closed wounds 92.4 per cent healed by primary intention.

Twenty five per cent of the deaths following cholecystectomy occurred in patients 65 years of age or older but this group was only 7 per cent of the cholecystectomies.

SAMUEL KAHN, M.D.

Hepatic Abscess: Factors Determining Its Localization. THOMAS D. KIRKNEY and JOSEPH W. FERRELL. *Arch. Path. Chlc.* 1948, 45 41.

It has been known since Serege's work in 1901 that the blood in the portal vein is relatively un-

mixed. The column from the superior mesenteric vein enters the right lobe of the liver and the column from the combined splenic and inferior mesenteric areas enters the left lobe of the liver.

The authors reviewed a series of 39,219 autopsies which disclosed 263 hepatic abscesses. Records for 229 only were complete and these form the basis for this report.

In 136 cases abscesses were present in both the right and left lobes of the liver in 75 cases the right lobe only was involved and in 18 cases the left lobe only was involved. The source of the infection is listed for each case.

Infection following common duct obstruction with septicemia was the chief cause of hepatic abscess. Eleven cases were due to abscess primary in the liver. Abscess formation in the left lobe alone was rare and in over half of the instances was due to direct extension of an ulcerating stomach lesion or infection of the lesser peritoneal cavity. There were 12 instances of abscess of the right lobe alone associated with inflammation of the gall bladder.

Hepatic abscesses following appendicitis tended to occur in the right lobe only unless there was an associated portal pyelophlebitis. If this occurs multiple lesions in both lobes usually result.

Abscess of the right lobe alone occurred in 27 patients in whom the primary focus of infection lay in an area drained by the superior mesenteric vein. Serege's rule appeared to hold with only one exception. In 4 cases the portal blood mixed sufficiently to result in bilateral liver abscesses.

The two lobes of the liver arise from separate outpouchings of the upper enteron and retain anatomic independence particularly with regard to the vasculature. There is evidence that the streams of portal blood coming into the lobes are of somewhat different origin. In man it is recognized that processes metastasizing via the superior mesenteric vein tend to go to the right lobe while processes coming from areas of the inferior mesenteric coronary and splenic veins go to the left lobe. The short portal trunk, low pressure, and sluggish flow may prevent complete mixing of the blood.

It has been suggested that there is a distinction between the nutritional environments of the two lobes in man. Since portal blood comes to the right lobe from the small intestine predominantly it may be richer in protective protein products of digestion than blood entering the left lobe. Separate catheterizations of the hepatic veins and study of the compositions of the blood leaving the right and left lobes would be of interest and might shed light on this problem.

ROBERT R. BIGELOW, M.D.

Cholecystectomy without Drainage (La cholecystectomie sans drainage). P. MALLET GUY and R. KOFFER. *Lyon chir.*, 1947 42 543.

The omission of drainage in 116 cholecystectomies was followed by no instance of hemorrhage, infection or biliary peritonitis. One patient died from pulmonary embolism, a mortality rate of 0.85 per cent.

The authors contend that omission of drainage following cholecystectomy permits better healing of the wound and a more rapid and satisfactory convalescence. They warn that it is essential to ligate the cystic duct with nonabsorbable material that no pathologic condition of the cystic duct may exist as it will jeopardize the security of the ligature, and that complete hemostasis of the gall bladder bed should be achieved with the electrocautery.

Forty-nine cases were followed up for a year or more. The results were classified as perfect in 44 good in 2 and mediocre in 3.

EDWARD W. GIBBS, M.D.

Dystonia of the Common Bile Duct (Les dystonies de la voie biliaire) R. GUILLET, *J. chir. Par.* 1947 63 554.

Following a brief discussion of the anatomy and physiology of the triple system of sphincters of the adult choledochus, it is emphasized that dystonias of the common duct cannot be recognized clinically. Recent radiomanometric studies have shown hypotonia to be almost as common as hypertonia. There are only some 87 cases of hypotonia of the choledochus with radiomanometric findings available for study, namely the series by Mallet-Guy. Dystonia of the sphincter of Oddi is rarely primary and is usually associated with some pancreatic or biliary lesion. Sphincteric atony may produce pictures not only of pure angiocholitis, but also of medical jaundice recurrence following cholecystectomy or even chronic cholecystitis. Pancreatitis of obscure origin must be differentiated from a pancreatic reaction to atony of the sphincter of Oddi. In all of these cases, it is imperative to treat not only the consequences of the atony but the atony itself.

Caroli's apparatus reveals in cases of hypotonia in this region subnormal filling, evacuation and stabilization pressures. Mallet-Guy's apparatus shows a characteristic curve, with a rapid almost immediate fall in pressure and a subnormal stabilization level of from 8 to 6 cm. or even less. To be valid this curve must appear unchanged in at least two tracings. The essential roentgen feature is the wide or even gaping sphincter.

External derivation (cholecystostomy or choledochotomy) may relieve mild dystonias and affords opportunity for later correction of erroneous diagnosis, but many cases fail to respond to this method. Mallet-Guy suggests sympathetic intervention with unilateral or bilateral splanchnic infiltration or splanchnicectomy. The latter is most often used unilaterally by the subperitoneal route, is easy and safe and presents almost no contraindications. It can, moreover be performed at the same time as exploration of the bile tract.

Medical treatment, duodenal drainage or even splanchnic infiltration is rarely indicated except in cases showing a barium reflux. In atony associated with angiocholitis, a dilated choledochus, and infected bile, external drainage is in order but choledochotomy carries the risk of duodenal reflux and is

best combined with splanchnic infiltration. Mallet-Guy avoids drainage unless the angiocholitis is very severe, preferring an immediate right splanchnicectomy. Very mild cases may respond to external drainage. When the complication is a calcareous cholecystitis, removal is indicated with eventual transcutaneous drainage or even splanchnicectomy. Cases of pseudorecurrence and atony in which both angiocholitis and atony have to be treated by drainage of the choledochus or of the cystic stump (frequently dilated into a "neo-gall bladder") require splanchnic infiltration or right splanchnicectomy. Atony of the choledochus in medical jaundice likewise requires drainage and eventual intervention on the sympathetic system. In chronic pancreatitis with atony splanchnicectomy is doubly indicated.

Hypertension of the choledochus leads to stasis with resulting angiocholitis and dilatation of the hepatocholedochus, with final repercussions on the liver cells. Persisting hypertension may produce lesions which maintain and exacerbate the hypertension. Manometrically purely functional hypertension may respond to vagolytic drugs for a time, or persist and become worse because of local hypertrophy and sclerosis. The only reliable method of diagnosis is radiomanometry.

Hypertension may follow cholecystectomy, or chronic cholecystitis with or without exclusion of the gall bladder or lithiasis of the common duct. In chronic cholecystitis with exclusion of the gall bladder a supplementary sphincterotomy will be needed. Cholecystectomy constitutes only a part of the surgical problem in choledocholithiasis. The condition of the sphincter of the choledochus will determine the immediate and late results. It is imperative in all cases, following removal of the calculi, to verify the state of the sphincter. Hypertension of the choledochus, especially if associated with sclerosis, may cause biliary fistula or recurrence following external derivation. Radiomanometry may disclose such hypertension as the cause of pseudolithiasis syndromes. Most frequently physiopathologic reverberations of hypertension may be observed in the gall bladder, pancreas or even in the liver cells. One may thus have to consider atony of the gall bladder, chronic pancreatitis, medical jaundice or sclerosis of the sphincter in association with hypertension. If sclerosis is present it must be determined whether it be primary or secondary.

Hypertension and sclerosis of the sphincter produce the same symptoms, but the former yields to indirect medical, or neurolytic methods, while the latter demands direct surgical intervention.

In hypertension of the choledochus or sphincter of Oddi, cholecystography reveals an abnormally tonic gall bladder with visibility of the cystic and even of the common duct following ingestion of a fatty meal. Only radiomanometry will confirm the diagnosis. Manometry by vesicular puncture will not suffice, but with puncture of the choledochus yields characteristic pictures with the Caroli apparatus, showing an abnormally high pressure (above 15 or 16 cm.)

for filling and stabilization. The Mallet Guy curve is abnormal and the residual pressure above normal. The roentgenographic findings are not pathognomonic. It is only their association or coexistence with radiomanometric findings which serves for diagnosis of hypertension of the common duct. The distinction between pure hypertension and hypertension with sclerosis is extremely difficult. The suspicion of even a beginning sclerosis justifies surgical intervention.

The treatment of hypertension of the choledochus consists of direct or indirect intervention on the sphincter. The former seems most logical. Mallet Guy's transduodenal sphincterotomy is done with the manometer *in situ* which aids in localization of the papilla. It permits control of division of the sphincter and avoids complete severance which might lead to reflux and ascending angiocholitis. An infiltration of the vagus nerve during operation may serve to distinguish functional from anatomic hypertension. Even though medical therapy succeeds in a few cases a correct diagnosis is possible only with interoperative manometry. If the bile tract appears normal, radiomanometric study via puncture of the gall bladder is indicated with suture at the end of the operation—sphincterotomy without drainage. If cholecystectomy is indicated as for lithiasic cholecystitis the radiomanometric examination is done via intubation of the cystic duct, which likewise is sutured at the end of the operation. This is likewise sphincterotomy without drainage. However in the presence of angiocholitis, a drain is inserted into the common duct. Should choledochotomy be indicated following a previous cholecystectomy the drain is left in the choledochus above the level of the sphincterotomy for 1 or 2 weeks. Medical treatment constitutes an excellent adjunct to external derivation. Failures and recurrences are common after both external and internal derivation. The causal therapy is partial sphincterotomy. Although immediate results are encouraging late results must await future evaluation.

In generalized atony unilateral right splanchnicectomy is recommended. The author prefers a direct attack with sphincterotomy under manometric control. Even though generalization of hypertensive phenomena might seem to justify vagotomy following anesthetic infiltration tests the possibility of sclerotic lesions indicates the direct attack. Only radiomanometric examination will permit localization of a functional disturbance and occasionally reveal its cause. This diagnostic method constitutes a great step in advance but it may be still further developed.

EDITH SCHANCHÉ MOORE.

The Significance of the Choledochus Syndrome of Villard (Du déterminisme du syndrome cholédocien de Villard) P. MALLET GUY and R. LACOUR. *Lyon chir* 1947 42 683

The triad of pain, fever, and icterus proposed by Villard in 1913 as diagnostic of stone in the common duct was found to be present in 147 of 515 patients

complaining of biliary symptoms. Of these 106 presented the typical triad, 17 exhibited icterus and one of the other two symptoms, and 26 showed in addition to the typical triad either symptoms of angiocholitis or of prolonged persistence of the icterus. The groups are designated respectively the typical form, the subdeveloped form, and the reinforced form. With the authors' methods of roentgenologic control and of manometric measurement of pressures in the bile passages, carried out during the operation itself, the presence of stone in the common duct was confirmed at operation in 61 patients who exhibited the syndrome of Villard, either in its typical form (46 cases), subdeveloped form (4 cases), or reinforced form (11 cases). In 14 more instances (12 typical and 2 subdeveloped) there was either positive certainty or at least strong likelihood that the common duct stone causing the symptoms had passed on into the duodenum. Thus there was a total of 75 cases (51 per cent) in which the cholelithic significance of the syndrome was confirmed either with certainty or with strong likelihood. Then there were 21 patients (14 per cent) in whom the presence of choledocholithiasis at one time or another was possible and 51 (35 per cent) in whom a hypothesis of choledocholithiasis seemed unlikely or impossible.

However although it is shown that there are a large number of conditions other than stone in the common bile duct which can reproduce in whole or in part the syndrome of Villard, the approach is still surgical. It is only when the abdomen is opened and the biliary system exposed that the manometric and roentgenologic controls can be carried out and only by means of these controls can the diagnosis of calculus or of any other pathologic condition be made with certainty. These controls can be applied in a few minutes by simple puncture. If the gall bladder appears to be normal or by intubation of the stump of the cystic duct if the gall bladder must be sacrificed. They will permit the detection of stones which cannot be palpated such as very small stones at the papilla of Vater which are masked by pancreatic reaction or disease. The methods also assure the removal of the obstruction and in cases in which stone is not present in the main biliary passage they will obviate an unnecessary choledochotomy. If biliary drainage seems to be the proper treatment for the condition present transcystic drainage may be simply substituted for the transcystic intubation.

JOHN W. BRENNAN, M.D.

Pancreatic Calculi E. L. ELIASON AND ROBERT F. WELTY. *Ann Surg.*, 1948 127 150.

Pancreatic calculi occur much more commonly than is generally appreciated. They can readily be recognized by roentgenologic examination. Surgical relief can be obtained and surgery is the procedure of choice in severe cases.

During a 10 year period from 1936 to 1945 9 cases of pancreatic calculi were admitted to the services of the senior author at three hospitals. All of the patients were explored. One patient died in this series.

a mortality of 11 per cent. Of the remainder only one was not definitely benefited, although some continued to have slight residual symptoms.

CHARLES BARON, M.D.

Fibrocystic Disease of the Pancreas: A Review of 14 Cases. DAVID PITT. *Med J Australia*, 1943, 1: 9.

The main clinical features of pancreatic fibrocystic disease are undernutrition, steatorrhea and chronic respiratory infection. The process is essentially a deficiency disease, the deficiency being in the external secretion of the pancreas. Familial and hereditary tendencies are recognized. The central theme of this report concerns the clinical résumé of 14 children manifesting this disease syndrome.

The initial symptoms were abdominal in about half of the cases and respiratory in the remainder. Bowel abnormalities were commonly noted often with bouts of diarrhea and the passage of large pale stool usually offensive in odor. Respiratory symptoms included cough present in some instances since birth. It was usually dry at the onset becoming moist only when purulent bronchitis or bronchiectasis supervened. Recurrent upper respiratory infections, bronchitis, and bronchopneumonia were almost invariable. Clubbing of the fingers was noted in 8 instances and cyanosis (a bad prognostic sign) was a common feature in advanced cases. Nutrition was uniformly defective being manifested by celiac facies, potbelly, wasted thighs and buttocks, poor muscle tone, and loss of subcutaneous fat.

In 5 of the 9 fatal cases enlarged and fatty livers were noted. Other workers have shown that defective pancreatic function is associated with fatty accumulation in the liver which in patients who survive gives place to a multilobular type of coarse cirrhosis.

The clinical diagnosis of fibrocystic disease of the pancreas should be made whenever the celiac syndrome is associated with evidence of lung disease. Estimation of the fat content of the stool should be carried out when clinical suspicion of the disease is aroused. The author mentions multiple diagnostic procedures designed to differentiate fibrocystic disease from celiac disease.

In untreated fibrocystic disease the course is steadily downhill. Just as the pancreatic lesion is progressive so is the pulmonary condition, and it is this which determines the death of the patient. When the early bronchitic phase is overtaken by the later infective phase the child is caught in an irreversible chain of events which leads to a fatal termination.

Treatment consists of diet, the administration of pancreatin, a generous vitamin intake, and control of the upper respiratory infections. The caloric intake must be carefully watched and a high caloric, protein rich, and restricted fat diet planned. Vitamin A should be given parenterally, the other vitamins orally. Penicillin and sulfonamide therapy is used for the recurrent pulmonary infections.

ORVILLE F. GUNDS, M.D.

Cystadenoma of the Pancreas. EDWARD E. JOHNS and NORMAN A. SAMUELS. *A. & S. Surg.* 1943, 1: 173.

A cystadenoma of the head of the pancreas in a 31 year old female which had compressed the residual tissue of the head into a thin shell intimately applied to its posterior aspect, was successfully removed. The common bile duct, portal vein, and hepatic artery which were flattened out and bound to the posterior aspect of the mass were dissected free. Of note was the absence of any evidence of common duct or portal vein obstruction despite the marked compression of these structures. The location of this tumor in the head of the pancreas is uncommon in a lesion which in itself is infrequent. The mass was markedly mobile and because of this and the absence of any suggestive roentgenologic findings, a preoperative diagnosis of pancreatic cyst was not made. The mobility was due to an unusually displaceable duodenum and pancreatic head. It was noted, fluoroscopically that the duodenum was situated to the left of the midline but as there was no evidence of its compression or distortion the significance of the finding was not interpreted as suggesting a pancreatic lesion. The tumor itself was firm rather than cystic to palpation and on section there was a considerable fibrous stroma between the numerous small cysts with a large, central solid mass containing calcific deposits. The epithelium lining the cysts in some areas bore a marked resemblance to endothelium. It is interesting that despite this presence of calcium in the mass no shadow was cast on the roentgenograms even when the films were reviewed in retrospect.

The literature on cystadenoma of the pancreas was reviewed, and the various clinical, pathologic, and surgical features of the lesion were briefly discussed.

CHARLES BARON, M.D.

Spontaneous Rupture of the Malarial Spleen. FALLS B. HERBERT and JOSEPH M. LUTZKE. *Ann. Surg.* 1943, 7: 40.

With the large number of malarial cases in the military service, traumatic and spontaneous rupture of the large friable spleen has become more common. The authors in reviewing the literature since 1917 have found 64 cases and prior to that time 73 cases were reviewed by Leighton. Many of these cases occurred in inoculated patients.

The authors give a detailed report of the case of a 37 year old veteran who recovered after surgical removal of a spontaneously ruptured malarial spleen.

In the series of 64 cases reviewed 39 occurred in inoculated patients and 25 in naturally acquired malaria patients. In the inoculation malaria the incidence of rupture varied from 1 to 101 to 0.5000 cases. Rupture occurred as early as the second day and as late as the fifteenth day of illness in this group. Traumatic rupture of the malarial spleen is very frequent (93 of 123 cases).

Spontaneous rupture of the spleen in naturally acquired malaria is rare. Although rare, prompt diagnosis and treatment will save persons who would

otherwise die. Spontaneous rupture of the spleen has been reported with all species except *Plasmodium malanæ*, the great majority of ruptures occurring in cases with *Plasmodium vivax*.

The spleens were enlarged averaging from 450 to 500 gm. Hemoperitoneum was present in all but one case and was almost uniformly due to rupture of the capsule. The pathological descriptions of the spleens were similar and followed the description of the spleen of acute malaria. The authors emphasize how reticular and endothelial hyperplasia obstruct venules and sinuses and cause the interstitial and subcapsular hemorrhages that often lead to rupture.

The mechanism of rupture may be due to (1) local lesions as points of weakness (2) increase of tension due to hyperplasia and engorgement and (3) compression by the abdominal musculature.

Arteriosclerotic alterations in vessels adhesions and thickening of the capsule, interstitial and subcapsular hematomas, focal necrosis changes in fibrous tissue or blood vessels, and great increase in tension within the capsule all may be responsible for the rupture. Vomiting, diarrhea, defecation and straining all may be of significance.

The signs and symptoms are chiefly those of (1) circulatory effects of acute blood loss and (2) local abdominal effects of bleeding and rupture. The authors call attention to the different clinical picture in lactics and nonlactics. The lactics were older and afebrile they had negative abdominal findings and acute malaria and usually died less than 2 hours after onset of the symptoms often with no complaints of pain. All but one of the nonlactics had pain and collapse. The onset of rupture was sudden and clear in all but 2 cases. The pain was severe generalized and worse in the left or upper abdomen. Kehr's sign was present in only 6 cases. Epigastric abdominal spasm tenderness slight abdominal distention and persistent left flank dullness were the chief abdominal findings. The spleen was palpable in only 5 cases.

Preoperative malarial smears were positive in all 8 cases in which they were made. The white blood counts were low or only slightly elevated. In 5 cases the preoperative hemoglobin was low.

The diagnosis was made preoperatively in only 7 cases and suggested in 2 others. Perforated peptic ulcer intra-abdominal hemorrhage ruptured hollow viscus intra-abdominal abscess and ruptured uterine tumor were other diagnoses listed. Cerebral malaria and cardiovascular accidents were the most frequent diagnoses made when malaria was known to be present.

The absence of an ulcer history the normal leucocyte count plasmodia in the smear a not exceedingly rigid abdomen, absence of free air under the diaphragm and physical findings and symptoms pointing to the left upper quadrant are all helpful in differentiating a perforated ulcer.

In the absence of shock and presence of malaria one must consider perisplenitis splenic infarctioo splenic abscess, and volvulus of the spleen.

The treatment is always surgical as this complication is almost always fatal. Prompt restoration of the blood volume is essential. The operative mortality varies from 26 to 33 per cent in the natural and inoculated malaria. Accurate early diagnosis results in lowered mortality and reduced postoperative complications. Better medical and antishock treatment may improve the surgical mortality.

In this series 5 patients died and 14 survived. Splenectomy was the treatment in every successful result. Generous blood transfusions have been used recently with success. Adequate medical treatment of the malaria is essential.

ROBERT R. BIGELOW M.D.

Hemolysis by Splenohemolysin as Manifestation of Splenopathy of Regressive Character (*L'emolisi da splenemolisi come manifestazione di splenopatie a carattere regressivo*) C. TARANTINO and F. PASQUINELLI *Sperimentale* 1947 98 563

Various theories favoring or criticizing the hypothesis of the existence of hemolysins of splenic origin are discussed by the author.

In patients with splenic disorders a ligation of the splenic artery may replace splenectomy whenever the size of the organ adhesions, or general condition of the patient preclude removal of the organ.

A diagnosis of Banti's syndrome was made in a 54 year old man with an enlarged spleen hemolytic icterus and ascites. A ligation of the splenic artery and omentopexy were performed. The histologic examination confirmed the diagnosis of Banti's disease.

Two months after the operation the patient again developed hemolytic jaundice.

The author concludes from his observations that the spleen secretes a hemolysin which may display its effect in remote areas.

The Pneumoperitoneums of Unknown Origin (*Les pneumopéritoneaux d'origine inconnue*) GEORGE PROVOT and LUCIEN LEGER. *J. chir., Par* 1947 63 632

Two cases of pneumoperitoneum are reported. The first patient was a 30 year old female who suddenly experienced violent pain in the epigastric region. Under bed rest the pain disappeared except that there was pain on coughing which radiated to the right shoulder. Roentgen examination disclosed pneumoperitoneum. (The patient had been taking baking soda for about 2 weeks for digestive distress.) Some pain was experienced on palpation in the epigastric and right hypochondrial regions. Since the condition did not change in 2 days an exploratory operation was decided upon. This was done under spinal anesthesia. Nothing abnormal was found except the air in the peritoneal cavity however during the operation the patient suffered cardiac and respiratory arrest (anesthesia accident) and despite the assistance of a respirator died 4

hours later. At autopsy the duodenum appeared somewhat flaccid the external surface was ecchymotic and the inner surface was of a dark brownish color. Nothing else seemed to be abnormal.

The second case was that of a 33 year old man. About 2 hours after the evening meal he experienced a sudden violent abdominal pain. This was located mostly on the left side but radiated to the right shoulder. The abdomen became enormously dilated but did not contract. The liver dullness completely disappeared. Palpation provoked a rather severe pain in the right iliac region. Aside from a lead line on the gums and the pneumoperitoneum no other abnormality could be found however about a month previously he had had another such pain attack, this time on the right side with the pain radiating to the left shoulder, and he had vomited and suffered a temporary retention of gas and feces. This time also he had been hospitalized and pneumoperitoneum had been demonstrated roentgenologically. In the second attack operation was decided upon and upon opening of the peritoneal cavity there was a gush of stale smelling gas. The intestines were also somewhat dilated and in the region of the appendix there was a small pool of a slightly turbid fluid with the same stale unpleasant odor as the gas. The fluid proved sterile and there was no explanation for its origin or for the origin of the pneumoperitoneum. Two months later the patient had another attack of the same general character as the preceding ones, and died without consulting a physician. There was no autopsy.

In connection with these 2 cases the authors reviewed the literature on the subject of pneumoperitoneum and were able to gather 53 fairly comprehensive case reports. In 31 of these operation was done 20 patients recovered and 11 died. The remaining 22 patients were not operated upon and all recovered except 1 who appeared not to have died of the abdominal condition. These figures do not argue in favor of exclusive medical treatment of pneumoperitoneum however they emphasize the urgent need of intense study of the so-called idiopathic form of pneumoperitoneum and the danger of a priori reasoning.

In fact no one form of etiology seems to explain all cases some seem reasonably well explained on the basis of a microperforation of the stomach or duodenum, or of tubal antiperistalsis in the female or of a perforation into the peritoneal cavity of a subcutaneous or mediastinal emphysema or of the rupture of cystic pneumatosis or of manual perforations of the uterus or bladder. Yet the abundant occurrence of these etiologic possibilities (except perhaps the cystic pneumatosis) when compared with the rarity of spontaneous pneumoperitoneum, does not argue for any close relationship among them, and the authors believe that it is best to regard pneumoperitoneum as resulting from a number of different etiologic factors until such time when something more can be learned of its pathogenesis.

JOHN W. BARKMAN, M.D.

A Contribution to the Study of Mesenteric Cysts
(Contributo allo studio delle cisti del mesentero)
GIOVANNI D'ENRICO. *Riforma med.*, 1947, 61: 333

A review of the literature is presented and mesenteric cysts are classified according to Bonacconi into lymphatic, embryonal, and parasitic types. The author then gives a description of all these types and discusses their etiopathogenesis and pathological anatomy. Two case reports are presented one of a lymphatic cyst found while operating for an ovarian cyst both cysts were excised. The second report was of a dermoid cyst. The clinical signs were described they being essentially those of a freely movable mass in the right side lateral to the umbilicus.

The number of reported cases according to Coster Kellner and Escue is less than 400 (1946).

LEUCIAN J. FROSTON, M.D.

One Hundred and Thirty-Seven Consecutive Combined Abdominoperineal Resections without Mortality THOMAS E. JONES, JOHN R. ROBINSON, and GARRETT B. MEADS. *Arch. Surg.* 1948, 56: 109

Since the treatment of carcinoma of the rectum is still a controversial subject in the medical literature the authors presented a study of 137 consecutive combined abdominoperineal resections of the rectum without operative mortality as a contribution to the growing weight of evidence in favor of the one stage combined abdominoperineal resection, as contrasted with operations of lesser magnitude. A Miles type of operation was performed in all cases under spinal anesthesia. The wounds were closed primarily with alloy steel wire sutures. No sulfonamides or antibiotics were employed in the preparation of the patients or at the time of operation.

Of interest is the observation that 28 of the patients complained of hemorrhoids within a period of about 6 months prior to the diagnosis of a malignant growth, and in 75 per cent of these hemorrhoidectomy had been performed in the same period.

There is no standard set of symptoms for rectal carcinoma the patient's history alone is unreliable. The duration of symptoms before a proper diagnosis is made depends on 3 factors: (1) the patient's neglect in not consulting a physician before the condition is in a far advanced stage; (2) disregard of good medical advice; and (3) improper diagnosis of the condition in its early stages. The greatest number of patients in this group (75 per cent) had symptoms for 9 months or longer only 25 per cent had symptoms from 1 to 9 months.

A palpable rectal lesion was elicited on digital examination in 120 patients (87 per cent) in only 28 patients (13 per cent) was a sigmoidoscopy required in making the diagnosis. The sigmoidoscope was otherwise utilized to determine the amount of circumference of the rectum involved by the lesion, the amount of fixation of the lesion, the character and type of ulceration of the mucosa, and the distance of ulceration from the mucocutaneous junction.

Biopsy was carried out only once in the present series. The authors are not of the opinion that it is

opsy is necessary since the diagnosis can be made on gross appearance of the lesion and it may even be misleading. Often biopsies of superficial tissue do not reveal the disease when a biopsy of tissue from deep in the tumor would.

Preoperative fixation was noted in 41 cases (29 per cent) but fixation at operation was encountered in only 38 (about 27 per cent). In 14 of these it was necessary to remove a portion of the prostate with the rectal growth. Radium seeds were implanted in to this prostatic bed or in the surrounding tissue in 6 of the 14 patients. Nodules in the liver were encountered in 9 cases. Metastatic glands were found in 4 patients in whom the operation was performed primarily for the comfort of the patient.

The most important indication of the patient's condition during operation was the pulse rate. Increases in pulse rate were viewed with much more alarm than drops in blood pressure.

In 3 cases two separate lesions were found in the same specimen, the lesions in 2 patients being an adenocarcinoma in the rectum and a squamous cell carcinoma at the mucocutaneous junction. Mucosal polyps separate from the malignant lesion were found in 30 cases (22 per cent). In 8 of these there were multiple mucosal polyps. The pathologic classification and the number of the lesions were: 125 adenocarcinomas (90 per cent), 5 medullary carcinomas (4 per cent), 4 squamous cell carcinomas (3 per cent) and 4 benign papillomas with malignant change (3 per cent).

The entire series of lymphatic nodes was involved in 7 cases (5 per cent). The perirectal fat only was involved in 49 cases (35 per cent). The fat and nodes were both involved in 67 cases (40 per cent). In 15 cases there was no involvement of the fat or nodes. In the smallest lesion there was no involvement of the fat but there was involvement of 14 per cent of the nodes. In the largest lesion there was involvement

of fat but no involvement of nodes. Hence the relationship of the size of the lesion to its spread to the surrounding structures remains undetermined.

The authors believe that the one factor responsible for a marked reduction of complications is the employment of alloy steel wire sutures through all layers in closing the abdominal wound. Infection of abdominal wounds occurred in only 3 cases (2 per cent). The other factors in lessening complications were (1) the avoidance of stay sutures of any type and (2) the avoidance of suturing the serosa of the bowel to the peritoneum or the abdominal wall.

An uneventful postoperative course, except for disturbances of the urinary tract, occurred in 68 cases (48 per cent). Mild obstruction of the small intestines or paralytic ileus developed in 13 cases (9 per cent) and was relieved in all cases but one by the use of the Miller Abbott tube enterostomy for relief was required in the one exception. Pulmonary infection occurred in 2 patients and atelectasis in 4. Mild infection of the posterior wound occurred four times. A fistula in the posterior vaginal wall also occurred in 4 cases. Infection of the urinary tract and retention of urine were very troublesome and most consistent.

The reviewer desires to call particular attention to the departure by the authors from the generally accepted preoperative use of sparingly absorbable sulfonamide drugs and the omission of biopsies.

In the discussion of this paper Maddock stated that while cancer is a disease that is never treated too early and seldom too radically, yet he is dissatisfied with the opinion that all rectal carcinomas should be subjected to a Miles procedure with the consequent loss of the anal sphincteric control. It is his belief that in patients with liver metastases the function of the sphincter should be preserved as the length of life in these patients is relatively short.

ROBERT TURELL, M.D.

GYNECOLOGY

UTERUS

A Method of Study of the Uterine Canal. W. B. NORMENT South. Surgeon 1947 3:883

This article deals entirely with the diagnosis of submucosal myomas, polyps and malignancy of the fundus of the uterus by means of hysterograms and direct observation. Since the uterus is such a common site of polyps and submucosal myomas it would seem that a hysteroграм should be almost a routine requirement in case of irregular uterine bleeding.

The objections to the use of iodized oils are overcome by the use of rayopaque. This product is an opaque contrast medium containing an organic iodine compound and a polymetric form of alcohol. The author uses a plastic cannula which is semipliable and nonopaque. The technique of injection is presented.

The second method of study is by direct vision and indirect vision. This is more useful in detection of carcinoma of the fundus of the uterus. The instruments consist of a transparent plastic sheath and an optical instrument which is inserted into the plastic tube. Some type of anesthesia must be given. The cervical canal is dilated and the plastic tube with the optical instrument is inserted into the uterus. If it is sufficiently evident that carcinoma is present, then curettage is not necessary. If there is doubt, curettage should be performed.

This method of study of the uterine canal, by hysteroграм with rayopaque direct and indirect vision combined, will aid greatly in the diagnosis of benign and malignant growths of the uterus, with greater safety to the patient. T. FLORE BELL, M.D.

Contribution to the Study of Uterine Cysts (Contributo allo studio delle cisti dell'utero) PIRAZO QUINIO *Riv Ital g n* 947 50° 3.

The author divides these rare cysts into true cysts, in which a preformed wall covered by epithelial or endothelial tissue delimits a closed cavity entirely or partially filled with varying material and pseudocysts in which the wall of the abnormal closed cavity consists of connective and fibromuscular tissue or of tissue proper to a neoplastic, fibromyxomatous, or sarcomatous formation which has undergone cystic transformation. He classifies true cysts into retention cysts, lymphatic cysts, dermoid cysts, embryonal cysts, which include those from ectopic residues of Wolff's bodies, remnants of the Malpighi-Gartner canal, and anomalies of development of Mueller's ducts; cysts due to epithelial dysplasias and discovered at various periods in life and aberration cysts caused by invagination of the peritoneal epithelium. He reports 3 cases of histologically proved true cysts of the uterus: the first was classified among those of muellerian origin and the second was considered as a peculiar type of lymphatic cyst.

In the first case the large cyst had the appearance of an accessory uterine cavity. Because of its site and the absence of any particular structure as the cyst did not originate from remnants of Wolff's bodies or of the Malpighi-Gartner ducts, or from inclusion of epithelial elements of the peritoneal serosa or endometrial aberrations (the cyst was clearly separated from the uterine cavity by a special layer), it seemed evident that it had originated from remnants of Mueller's ducts. This had taken place by means of diverticula which had lost their primary connection with the mucosa or defects of scission or of fusion of the two ducts which had remained enclosed in the muscular layer of an apparently well formed uterus. The cyst had nearly all the anatomohistologic characteristics of muellerian cysts: median location, delimitation by the fibromuscular walls like those which should constitute the true walls of the muellerian canal, internal lining with cylindrical, cubical flat and stratified pavementous epithelium with well marked deformities, the presence of numerous true papillae, the presence of smooth fibromuscular cells in the wall of the cyst, and, finally, a viscous serosanguineous fluid content. Among all these characteristics the true papillae and the evident deformities of the lining epithelium are those which justify the classification because they serve to differentiate cysts of muellerian origin from those due to remnants of the ducts of Wolff and of Malpighi-Gartner.

In the second case the large cystic cavity was made irregular by the presence of remnants of old destroyed septa, the walls of which were lined by an interrupted layer of endothelial elements resting on a thick lamina of tissue having a fibrillary structure rich in lymphatic partly dilated spaces and muscular fibers beyond which the uterine musculature was thinned by the distention of the cyst under the pressure exercised by its liquid contents.

From the clinical point of view the two cases offered no help for the diagnosis: the difficulties of which are practically insuperable because of the absence of specific history and of subjective and objective pathognomonic data. In fact, even if the objective examination suggests a genital cystic tumor it will not always be easy to determine whether it is an ovarian or paraovarian cyst, a hydrosalpinx or a hematosalpinx, or a uterine tumor and in this case whether it is a cyst or a pseudocyst. In general, cysts and pseudocysts of small size pass unnoticed or are mistaken for fibrous nodules, while those of marked size are confused with more common uterine or parauterine conditions and even with pregnancy. But except for the possibility of confusion with pregnancy and the consequences which may derive from it, missing the correct diagnosis is of little importance because the conditions which simulate uterine cyst lead to the same surgical treatment. Surgery is absolutely indicated because the evolution of these

benign tumors is not exempt from possible serious complications which include rupture, suppurative and torsion of the uterus and grave cardiac disturbances in exaggerated development of the cyst. According to the findings the intervention may consist of subtotal or total hysterectomy or simple removal of the cystic formation generally if the operation is performed in time before the occurrence of complications it does not offer any difficulties and carries a favorable prognosis

RICHARD KEMEL, M D

Ectodermal Invasion of the Myometrium (L'invasione ectodermale del miometrio) LUIGI DE GIORGI
Arch ostet gin 1947 52 211

The terms ectodermal invasion and chorionic infiltration are not synonyms, but refer to different anatomical substrata and have a different meaning. By the latter the author means various morbid processes such as placenta accreta, and he defines the former (in accord with Poso) as that morbid process characterized by dissemination of derivatives of the chorionic ectoderm in the maternal structure to such an extent that, even when the uterus is completely freed of the ovum, a large part of the element remains in the placental area. This morbid process is called syncytial endometritis by Ewing and atypical chorioepithelioma by Marchand.

The author reports the case of a multipara, 45 years old, who following an amenorrhea of 6 months expelled from the uterus a mass (a vesicular mole) which was followed by a persistent metrorrhagia. After surgical intervention i.e. total abdominal hysterectomy and bilateral adnexectomy the patient recovered completely. Macroscopically the uterus revealed on the posterior wall toward the fundus an area irregular in shape and dark red in color which was considered to be the nidus of the ovum. Microscopically the dominant features were ectodermal elements, mostly in colonies, occasionally scattered and characterized by zonal disposition with extension in the myometrium, nuclear and protoplasmic areas of regression and regeneration, leucocytic infiltration and glandular elements. These areas were defined by the author as areas of endometriosis.

In the interpretation of the case, the most important facts to consider are the quantity, quality and extension of the ectodermal elements and the complete absence of any vestige of villi. This excludes the possibility of postabortive endometritis.

The theory that the ectodermal elements suggest a neoplastic growth is refuted by the absence of atypical cells which usually invade the chorioepithelomatous centers and which represent active or degenerative centers of the blastomatoses. It is also to be noted that there is a lack of inflammatory reaction superimposed on the ectodermal elements. Another important observation is the predominance of various stages of protoplasmic and nuclear degeneration which suggests the regressive characteristics of the lesion. The lesion therefore must not be regarded as a syncytoma or syncytial endometritis which

is a transitional lesion with definite neoplastic characteristics. Correct interpretation of the case leads to correct therapy. In this case radical surgery was suggested by the multiparity of the patient and the uterine metritis as disclosed by the histological examination of the uterine scrapings.

Chorionic invasion of the endometrium signifies a uterochorionic pathological process found at any stage of pregnancy. It is characterized anatomically by a quantitative abundance of chorionic elements interspersed with areas of degeneration in the decidua basalis and in that part of the myometrium corresponding to the situs placentaris. Inflammatory changes and phenomena of necrosis and hemorrhage are also present. It is a regressive process and not a neoplasm of the chorioepithelomatous type.

JOSEPH M. A. PAPP, M. D.

Atypical Endometrial Hyperplasia Simulating Adenocarcinoma. EMIL NOVAK AND FELIX RUTLEDGE. *Am J Obst* 1948 55 46

The purpose of this article is to call attention to a group of benign hyperplastic lesions of the endometrium which may be and often have been mistaken for adenocarcinoma. While these lesions are actually hyperplastic in a general pathological sense they are very different in their histologic characteristics from the ordinary type of benign endometrial hyperplasia. The latter term has come to have reference in gynecologic literature to the Swiss-cheese type of endometrium characterized especially by disparity in the size of the glands, some being large and cystic, and some small with a rather abundant, compact stroma. The authors emphasize that the histologic picture presented by the ordinary Swiss-cheese hyperplasia does not in the slightest degree resemble that of adenocarcinoma. Also the ordinary hyperplasia as observed during reproductive life has no tendency toward malignant transformation.

The histologic appearance of any part of the endometrium is determined not only by the hormonal influence to which it is subjected but also by its own degree of sensitivity or refractoriness to the hormones in question. The degree of maturity or immaturity, ripeness or unripeness of the endometrium appears to be the most important factor in determining the degree of its receptivity to the ovarian hormones. The simple type of Swiss-cheese hyperplasia does not represent the only abnormal endometrial pattern which may be produced by excessive or prolonged estrogen stimulation. This atypical hyperplasia may be fairly uniform throughout the endometrium but more frequently the atypical lesion occurs in one or in many localized areas of an endometrium which otherwise presents an obviously benign Swiss-cheese picture. The authors believe that these abnormal cancerlike areas represent different degree or types of estrogen effect upon areas which respond differently to the same estrogen growth stimulus. This conclusion carries with it also the connotation that such areas are not histologically indicative of malignancy.

Some of the atypical proliferative patterns which may lead to the incorrect diagnosis of carcinoma are given as (1) increased number crowding and moderate atypicality of the glands (2) stratification, abnormal staining, and atypical morphology of the epithelium and (3) the presence of squamous plaques in the walls of the glands, and occasionally on the surface. These atypical patterns are discussed and illustrated.

The material forming the immediate basis for this study consisted of a group of cases, 44 in all, which showed atypical hyperplastic changes which might readily be mistaken for adenocarcinoma, and were selected from a considerably larger group exhibiting less pronounced atypical pictures which few would interpret as malignant. JOHN R. WOLFE, M.D.

Ultimate Results in Irradiation Treatment of Cancer of the Uterine Cervix (Sui risultati a distanza del trattamento atimico del carcinoma del collo dell'utero) ENRICO ROSECCO *Ginecologia, Tor.* 947 3 306

The author reports on 92 cases in which irradiation treatment was given for cancer of the uterine cervix in the period from January 1, 1934 to December 31, 1942. Eighty of these could be followed up from 3 to 2 years; those not followed up were simply figured as deaths. According to the Geneva classification 22.8 per cent of the cancers were adjudged as in the first stage, 33.9 per cent in the second, 31 per cent in the third, and 12.1 per cent in the fourth. By this classification the first two stages are regarded as operable and the last two as inoperable. The youngest patient was 31 years old and the oldest 66. Those regarded as operable were given the combined treatment with surgery and irradiation; the rest were given irradiation therapy alone. The latter method consisted of endocervical (10 mgm.) and vaginal (15 mgm.) applications of radium for a period of 8 days (total 4,800 mgm. hours) and then roentgen irradiation in doses of from 800 to 1,500 roentgens per field. There were two anterior and two posterior fields (rarely two trans-trochanteric fields) for a total dosage of from 3,200 to 6,000 roentgens. This course was repeated a second and third time at later periods.

After a period of 5 years' observation 60 per cent of the patients in the first stage, 50 per cent in the second stage, 21.6 per cent in the third stage and none in the fourth stage were still living. In those under observation for less than 5 years there were 6 in the first stage (3 living, 3 dead, 1 lost to follow up), 6 in the second stage (1 living and 5 dead) and 10 in the third stage (3 living, 6 dead, 1 lost to follow up). There were only 2 patients who were in the fourth stage: one of these died in 5 months and the other died a year later. Of course not all of the decedents died of their cancer; at least one is known to have died in an air raid and another of a pulmonary infection.

Thus, among the total 92 patients there were 23 with 5 year survivals and although one did die after

6 years and another after 8 years, the results obtained at this clinic (University of Torino, Italy) are regarded as exceptionally good.

The author regards the most important field for investigation at this time as that of earlier recognition of cervical cancer. JOHN W. BRENNAN, M.D.

ADNEAL AND PERIUTERINE CONDITIONS

Concerning Salpingography (Ueber die Salpingographie) HERMANN MARTUS, *Dtsch. med. Wschr.* 947 7 657

The author discusses the relative merits of the injection of air to test tubal patency versus the use of an iodized oil, and the roentgenological demonstration of the hysterotubal tract. He calls attention to the fact that the patient presenting herself for the diagnosis of sterility is an otherwise normal person, and, therefore, must be treated in a manner which will not do her any manner of harm. He believes that, in general, the injection of air is a far more innocuous procedure than the injection of the contrast medium. He believes that the larger number of complications reported following the former procedure is due to the fact that it is so frequently carried out in the offices of other than competent technicians and that it is all too often viewed as a simple office procedure.

One case is cited in which there were adhesions evidently following a hysterosalpingogram, and that separation of the adhesions disclosed small yellow masses which he believed were remnants of the iodized oil. The use of urographic media in water solutions has not been successful in his hands because of the lack of viscosity and rapid emptying from the fallopian tubes. Furthermore he believes that the radiation incident to the filming of the area should not be considered too lightly and that this may well cause harm to the ovaries and to the maturing ovum.

The author also points out that either procedure must be preceded by a careful gynecological examination made both manually and by observation through a speculum. He believes that as a therapeutic procedure the injection of air is preferable, as the iodized oil may of itself set up an inflammatory process, although this will probably take place only in an already diseased tube. WILLIAM C. BECK, M.D.

Studies of the Human Corpus Luteum. JOHN L. BREWER and HAROLD O. JONES. *Am. J. Obs.* 943, 55 18.

The purpose of this article is to present a histologic study of corpora lutea and endometrium in instances of functional uterine bleeding, and to discuss the relationships of these two tissues. Specimens are described and interpreted. The specimens in each instance were obtained by hysterectomy and oophorectomy or by resection of the corpus luteum. The operations were performed during the bleeding phase, since it is during this period that most accurate interpretations can be made.

The authors found that functional uterine bleeding may occur when a corpus luteum is present in the ovary. The endometrium in some instances may evidence irregular regression. The irregular regression is the result of prolonged life and function of the corpus luteum. The endometrial picture will vary depending upon the rate and extent of regression of the corpus luteum. The bleeding which occurs seems to be an exaggeration of the normal bleeding processes observed in cyclic menstruation.

The corpus luteum in other instances may be histologically and functionally normal. The endometrium, except in small regions, responds normally. It is from these small regions that bleeding occurs. The bleeding in these instances is independent of the corpus luteum and of the remainder of the endometrium. The bleeding is unlike the usual normal menstrual bleeding. It is localized bleeding from blood sinuses with scant loss of endometrial tissues. During this type of bleeding ovulation can occur corpus luteum development can progress normally and the endometrium not involved in the bleeding can develop normally. The phenomena that occur that produce the bleeding in such instances are not known. The explanation may reside in a local bleeding factor in the endometrium or in the local abnormality of response of the endometrium.

EXTERNAL GENITALIA

High Lymphadenectomy and Sympathectomy in Carcinoma of the Vulva. EDWIN M. ROBERTSON. *Am. J. Obs.* 1948, 55, 79.

The successful treatment of carcinoma of the vulva differs in no way from that of carcinoma in other sites in that the primary lesion, the spreading growth and the metastases in lymph nodes must be completely destroyed or eradicated.

Because the malignant vulvar tumor is situated on a part of the body which has an enormously wide spread lymph drainage system, the exact limits of surgical excision required are difficult to estimate as are the sites and dosage of radiation. However it seems that the radiation therapy of vulva carcinoma and lymph node metastases in the groin for example, is more limited than surgical excision of the affected parts and therefore vulvectomy and lymphadenectomy are the more favored procedures.

The author reports a case of carcinoma of the vulva occurring in a woman 37 years of age for which wide vulvectomy, bilateral inguinal and pelvic lymphadenectomy, right lumbar lymphadenectomy and lumbar sympathectomy were performed. The procedures are described.

It was not without very careful consideration that the accepted limits of surgical treatment of vulvar carcinoma were exceeded in this case but the relative youth of the patient, the large size and prolonged history of the growth, confidence in the safety of modern surgical procedures to avoid shock and infection and a hopeful confidence perhaps quite mis-

placed in concomitant sympathectomy as a means of lessening the chance of development of thrombosis and embolism were strong impelling influences.

The Detailed Anatomy of the Paraurethral Ducts in the Adult Human Female. JOHN W. HUFFMAN. *Am. J. Obs.* 1948, 55, 86.

Skene's presentation in 1880 established the clinical significance of the paraurethral ducts. However the extent and the detailed anatomy of these structures still remain a controversial matter and a review of the present day literature confirms Everett's statement that there is no unanimity of opinion on the subject of paraurethral and urethral glands. The purpose of this presentation is to describe the paraurethral ducts and glands of several adult human females in an effort to portray at least in part, the anatomy of the prostatic homologue in the female.

The material studied consisted of serial sections and wax model reconstructions of adult human female urethras. As a result of this study a concept of the anatomy and histology of the paraurethral ducts is presented. It would appear that these ducts are not constant in number or location that they not only form extensive ramifications throughout the tissues about the distal urethra, but that they may also extend to within a short distance of the bladder and that the often numerous ducts terminate in tubular glands which are lined for the most part by columnar epithelium. This epithelium has some at least though limited secretory activity.

The role which the paraurethral ducts may play in the etiology of lesions of the urethra and anterior vaginal wall is discussed.

Tumorlike Scleroses in the Submucous Connective Tissues of the Urethra in Women following Castration of the Menopause (Sclérose sous-urétrales pseudo-tumorales chez la femme castrée ou ménopausée). M. CHAMPEAU. *Rev. chir., Par.*, 1948, 67, 59.

A 75 year old woman, of fastidious personal habits had been suffering for about a month from delay slender stream and terminal dribbling with urination. There was some frequency of urination especially at night. There had also been some bleeding from the urethra. A thickened, dense mass was found extending the length of the urethra between this structure and the anterior vaginal mucosa. The mass was molded to the curvature of the urethral lumen. There was some eversion of the meatal mucosa (bleeding). Following a preliminary cystostomy the supposed tumor was easily excised and found to be composed exclusively of dense connective tissue. Four years later the condition recurred minus the bleeding. The urinary troubles were not so bad as originally.

Three other identical conditions have since been encountered, one in a 52 year old female who had

undergone a hysterectomy 4 years previously an other in a 61 year old woman in menopause for 10 years, and the third in a 46 year old woman who had undergone bilateral ovariectomy 4 years previously. In the last instance the condition was causing no symptoms.

In the 52 year old patient the mass was again easily excised and again it returned after 2 years, despite vigorous treatment with estrogens and progesterone including an implantation of 100 mgm. of folliculine.

In the 61 year old patient the sex hormones were again without effect and the mass was excised this time with difficulty which resulted in a small fistula that healed spontaneously after 3 weeks time. The patient did not return.

In the last patient the mass was not removed but later a hysterectomy was done and after that the urinary difficulties disappeared the tumor remaining unchanged.

The author believes this condition to be a hitherto undescribed manifestation of sex hormone deficiency and recommends prophylactic treatment with ovarian hormones in high dosage.

JOHN W. BREDMAN, M.D.

Care of Patients with Advanced Pelvic Cancer
WILLIAM E. COSTLOW *Radiology* 948, 50 3.

The author presents some generalized recommendations concerning advanced pelvic carcinoma.

Primary carcinoma of the vagina is considered by him a radiological problem at any stage, and from

85 to 90 per cent of all grades of cervical carcinoma are also considered entirely radiological problems. From 10 to 15 per cent of the cases are in stage I, and thus, may be considered operative. It is the author's belief that the operable types of corpus carcinoma should be given radium preoperatively.

The author believes that pelvic carcinoma should be considered a major medical and surgical problem. Attempts should be made to eradicate infection before treatment is commenced. Douches, sulfonamide drugs, penicillin and transfusions should be resorted to. X-ray therapy often aids in removing infection. Proper care regarding filtration, careful packing of the bladder and rectum away from the applicator and the use of retention catheters are greatly in this type of cancer therapy.

The most common complications in this region of the abdomen are cystitis and proctitis. Vagino-vaginal fistula occurs occasionally. Ureteral obstruction, when present, is almost always due to neoplastic disease but sometimes it is due to scar tissue in the parametrium. When severe pain complicates the picture, such surgical procedures as posterior rhinotomy, anterolateral cordotomy and presacral nerve section are recommended.

The radiation therapist should follow his patient up in co-operation with a general physician. There is increasing need for physicians thoroughly trained in cancer therapy who will follow up the advanced as well as the early case and thus administer the aid and palliation the patient needs.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

A Clinical and Histopathologic Study of Lesions of the Cervix Uteri during Pregnancy C. F. FLUK
MAYN *Am J Obst* 1948, 55 133.

An important feature of prenatal care is a careful inspection of the cervix uteri. This procedure often reveals pathologic lesions which exist with or without symptoms such as vaginal bleeding, and demand immediate attention. The object of this study is to present an analysis of the histopathologic findings in a series of 89 cases in which a gross abnormality was recognized and a biopsy of the cervix was obtained or a hysterectomy was performed. All stages of gestation are represented.

Gross and histopathologic examination revealed that mucous polyps of the cervix were found in 37 cases, erosion of the cervix in 32, carcinoma of the cervix in 10, condyloma acuminata in 5, endometrial polyps in 3, and leucoplakia in 2.

The generally accepted description of the cervix during gestation is that presented by Steve in 1927. The most prominent changes are to be found mainly in the connective tissue elements during the first 2 1/2 months. There is a tremendous increase in the number of blood and lymphatic vessels which continues throughout the whole of pregnancy so that eventually the cervix becomes a soft boggy structure comparable to erectile tissue. There is an increased activity of the cervical glands which is progressive throughout pregnancy, but does not become marked until after the twelfth week. From then on the glands increase in number, invade the substance of the cervix, and project into the cervical canal.

The gross and microscopic appearance of cervical erosion is described and its etiology is discussed. The present concept, advanced by Meyer and others, that all erosions should be considered the result of infection is not supported by the author's histopathologic analysis which suggests that these lesions should be considered as adenomas of the cervix. Extensive cervicitis was present in only 9 instances.

Although the largest group of lesions in the series were mucous polyps, originating either from the external os or from the cervical canal, bleeding occurred in only 6 instances.

Hyperactivity of the basal cell layers of the squamous epithelium and epidermalization occurred both in so-called erosions and in some mucous polyps. These abnormal proliferations are especially prone to occur during pregnancy and consequently there is here a wide field for further investigation and observation in view of the search for methods dealing with the recognition of early carcinomatous changes.

The subject of cancer of the cervix uteri during pregnancy is far beyond the limits of this article but as a matter of record some details are given

of the 10 cases of carcinoma of the cervix uteri during pregnancy observed in the Department of Obstetrics and Gynecology at the Stanford Medical School, San Francisco, California. JOHN R. WOLFE, M.D.

LABOR AND ITS COMPLICATIONS

The Expectant Management of Placenta Previa
TIFANY J. WILLIAMS. *Am J Obst.*, 1948 55 169.

The maternal mortality in placenta previa has been appreciably reduced in the past decade mainly by the replacement of blood loss by adequate transfusions of whole blood. On the other hand, fetal mortality remains high in a great measure because of prematurity. In order to improve the fetal results it is necessary to carry these patients closer to term. Ample, properly matched blood and caution in the use of vaginal manipulations may make it possible to continue the pregnancy until the child is larger and so increase the fetal salvage.

The author presents the results in 105 cases of placenta previa seen at the University of Virginia Hospital, Charlottesville, during the past 11 years. For 71 of these patients were treated in an expectant manner. Obviously there can be no expectant treatment once labor has begun. Likewise if the patient is at or near term there is no advantage in attempting to prolong the pregnancy.

Placenta previa requires hospitalization for diagnosis and treatment. In the event that the child seems too small to survive and if labor has not begun an expectant attitude may be adopted. A gentle examination and inspection of the vagina and cervix may be done to eliminate the possibility of some infrequent cause of bleeding such as ruptured varices or cervical tumors, but the cervical canal should not be explored. These patients should be kept under observation as were 41 patients in the author's series for periods of time varying from 2 days to 3 months in an effort to obtain a child which will survive. Five of the babies (12%) borne by these 41 patients were lost, one of these was delivered at term by cesarean section and died neonatally of congenital malformation, and 4 were born prematurely—one a stillborn and 3 dying neonatally. The fetal mortality in this group who were treated expectantly is considerably better than the fetal mortality of 28 per cent for the entire series.

The preferred methods of delivery were either cesarean section or induction of labor by rupture of the membranes according to the station of the presenting part, the degree of previa, and the condition of the cervix. The one maternal death is reviewed.

The author concludes that an attempt to carry patients with placenta previa to term seems to be reasonably safe and is worthy of trial although some of them will go into spontaneous labor prematurely while others will have such persistent or profuse

bleeding that one is reluctant to continue an expectant attitude.

JOHN R. WOLFE M.D.

Functional Dystocia following Cesarean Section through a Transverse Incision of the Lower Segment (Distocia funzionale conseguente taglio cesareo con incisione trasversale del segmento inferiore) GIOVANNI PAROLI *Riv. ostet. g.* 947 244.

A surgical problem always interesting and always open to discussion is whether a longitudinal or a transverse incision through the lower uterine segment is preferable in performing a cesarean section.

The transverse incision with modifications is held to be anatomically correct by most authorities. In the lower uterine segment, the majority of the muscle fibers run in a horizontal plane as do most of the blood vessels. A curved incision with the convexity downward is supposed to cause destruction of fewer anatomical structures.

Most authorities agree that regardless of the operative method the immediate results (danger to mother and fetus) and the remote results (resistance of the uterine scar in subsequent pregnancies) are equally good whether the longitudinal or the transverse incision is used.

Few reports have been made on the effects of cesarean section by the two methods on the functional activity in subsequent pregnancies e.g. motor activity and other dynamic phenomena.

In this regard 2 cases of dynamic dystocia following cesarean section through a transverse incision are reported and discussed.

The first case reported by the author was that of a 33 year old woman who was operated on by cesarean section through a transverse incision to terminate her fourth pregnancy on account of placenta previa. She had formerly had three normal deliveries. The postoperative course of the cesarean section was complicated by suppuration of the operative wound. A year after the section the patient entered the hospital in labor with the fetus in a vertex presentation the head not descending although the uterine contractions were strong. After 8 hours of labor the cervical dilatation was 5 cm. and the cervix was flexible. In spite of the soft sensation the cervix was asymmetrically dilated. The posterior lip of the cervix was more dilated than the anterior lip and during strong and regular uterine contractions the posterior lip stretched while the anterior one appeared flaccid and inert. After another hour of good contractions with pain essentially limited to the suprapubic region the local situation remained the same notwithstanding the fact that the fetal membranes had already ruptured. A diagnosis was made of arrested descent of the head and faulty cervical dilatation due to functional motor dystocia of the uterus. Manual dilatation was carried out and a classical podalic version was done without anesthesia. With the hand in the uterus while turning the fetus, a rigid semilunar band was felt in the anterior uterine wall at the site of the scar of the former transverse

cesarean section. A living fetus, weighing 3,500 gm was delivered.

Three years later the patient returned to the hospital 9 months pregnant. Dilatation of the cervix was incomplete. Manual dilatation was easily carried out. The head of the fetus was engaged, forceps were applied and a living fetus weighing 3,000 gm. was successfully delivered. The puerperium was normal.

Dynamic dystocia thus occurred in 2 successive pregnancies in a multipara who had formerly had 3 normal pregnancies and a fourth pregnancy terminated by transverse cesarean section.

The second case, presented by the author was that of a woman of 33 years who had undergone a transverse cesarean section to terminate her first pregnancy on account of a prolapsed cord. The postoperative course was complicated by suppuration of the operative wound. She entered the hospital for the delivery of her second child, the latter being in the oblique position. About one hour after entry the fetal membranes ruptured spontaneously. The uterine contractions were regular with complaint of pain in the suprapubic region. After 7 hours the cervix was dilated to the breadth of two fingers. After 18 hours, notwithstanding strong uterine contractions the dilatation was only 5 cm. with the anterior lip inert. The cervix was dilated manually forceps were applied and delivery of a living fetus weighing 3,500 gm. was accomplished.

Outstanding features common to both of these cases were difficult and incomplete dilatation of the cervix in spite of apparently normal uterine contractions without signs of cervical spasm difficult engagement of the fetal head with lack of progress of the presenting part the presence of suprapubic pain during uterine contractions instead of pain usually referred to the lumbosacral region and that both patients had had a cesarean section through a transverse incision in the lower segment followed by postoperative suppuration of the operative wound and the formation of a bandlike scar in the lower part of the anterior wall of the uterus.

Defective repair of the anterior wall of the uterus is believed by the author to be responsible for the dystocia in deliveries subsequent to a former delivery by transverse cesarean section. He holds that the longitudinal nerve pathways are interrupted by the transverse incision, and, as a result, during labor the normal nerve impulses, which give rise to the intersegmental uterine contractions are unable to pass to the lower segments of the anterior uterine wall and the anterior cervical lip. The dilatation of the cervix is interfered with and the descent of the fetus is arrested on account of failure of contraction of the lower uterine segment.

The transverse scar per se does not necessarily play a part in the dystocia, for while the majority of the muscle fibers of the lower segment are in a circular plane, some are oblique and some are longitudinal. When the scar is denser than normal on account of postoperative suppuration of the opera-

tive wound. It becomes the site of suprapubic pain during dystocia. Ordinarily the pain of childbirth is lumbosacral but that of the 2 cases reported was suprapubic. The author believes that the origin of infection of the operative wound of cesarean section is usually endouterine after faulty wound repair.

In conclusion, the author believes that the incision in cesarean section should be considered from a functional standpoint and not a purely anatomical one. Transverse incision should be reserved for those cases in which the longitudinal incision is definitely contraindicated (e. g., in the presence of midline tumors or abnormal bladder adhesions).

BLACKWELL MARKHAM, M.D.

NEWBORN

Premature Births. LEWIS A. KOCH, C. A. WEYMULLER, and ELIZABETH JAMES. *J Am M Ass* 1948 136 317

Prematurity is the leading cause of death in the newborn. In one-half of these newly born infants death occurs during the first 24 hours of life as the result of birth trauma and asphyxia during labor and delivery. The obstetrician's contribution to the reduction of this rate is twofold, namely attempted reduction of premature delivery and protection of the infant during labor and delivery.

A list of helpful suggestions are presented: (1) adequate supervision of the hygiene of pregnancy; (2) proper advice concerning diet, coitus, rest, and exercise; (3) immediate notification of the obstetrician whenever any untoward symptoms occur; (4) early discovery of syphilis and vigorous treatment for it throughout pregnancy; (5) prevention of congestive failure in cardiac disease through joint supervision by cardiologist and obstetrician; (6) determination of the size of the fetus by means of roentgenography and consultation with a competent obstetrician before interrupting pregnancy by artificial means; (7) elimination of morphine, scopolamine, barbiturates, and general anesthesia in all labors in which prematurity is involved; (8) administration of vitamin K to the mother before pregnancy is interrupted and to all premature infants immediately after birth; (9) preservation of the membranes as long as possible and episiotomy to protect the premature infant from the pressure effects of labor; (10) spontaneous delivery of the second twin and avoidance of version and extraction whenever possible; (11) postponement of the tying of the cord until it stops pulsating so that the child may receive as much blood from the placenta as possible; (12) reception of the newborn premature infant in a tub of warm water to prevent chilling while waiting for the cord to stop pulsating.

The authors discuss the pediatrician's role in reducing the mortality from prematurity. They outline their own technique and quote favorable clinical statistics to support their contentions. The delivery rooms are prepared for the reception of the premature infant, and a heated crib, facilities for the administration of oxygen, and a warm tub are available.

The nursery unit admittedly not ideal is so planned that each unit is as small as possible, consisting of 7 term babies and 1 premature infant. The care of infants in this unit is conducted by one nurse who does not handle any other babies. The danger of contact infection from visitors to mother to baby has been reduced by requiring all visitors to wear masks and gowns and by the use of rope barriers which prevent contact with the bed or bed clothes.

The personnel must have throat cultures; the nurses are required to wear a mask and gown and physicians and cleaning women are required to wear a mask, gown, and sterile gloves. All equipment is sterilized before it is placed in the unit and each unit is self-sufficient. Infected infants are removed immediately and no new babies are placed in that unit until the remaining babies have been discharged and the room has been thoroughly decontaminated. The authors stress the maintenance of adequate records on the progress of infants and at present house officers are more closely supervised than had previously been the custom.

From 1924 until 1940, 1,125 premature infants were born in the Long Island College Hospital, New York, New York, with a mortality rate of 28.4 per cent. Since the institution of the previously mentioned measures from 1940 to 1945, 637 premature infants were born with a mortality rate of 16.3 per cent, an overall improvement of 30 per cent.

JAMES F. DONNELLY, M.D.

MISCELLANEOUS

The Ectodermal Elements of the Situs Placentaris (Gli elementi ectodermici del "Situs Placentaris")
LUTCI DE GIROGI. *Arch ital gen* 1947 52 129

In the normal process of placentation, elements defined as ectodermic in nature are found in the ambit of the decidua basalis and of the myometrial strata. It is the intention of the author to study this phenomenon and its quantitative variations during the gravid state, its genesis and disappearance, also the behavior of these elements in cases with retention of placental tissue after abortion and delivery. He is also interested in the influence which certain pathological uterine conditions (myomas of the corpus uteri, carcinomas of the cervix of the uterus, chronic metritis) certain diseases of the ovary (tumors, ovarian cysts), various maternal diseases (tuberculosis, osteomalacia, eclampsia) as well as placenta previa and ectopic pregnancy will have on such elements.

After an accurate and meticulous revision and discussion of the literature, the author proceeds to report his cases, 36 in all, representing various stages of pregnancy and the puerperium. There were 8 cases of ectopic pregnancy and 20 cases representing uterine scrapings from postpartum and postabortive retention. He presents his conclusions from histological study of the situs placentaris.

In the ambit of the situs placentaris is to be noted the prevalence of elements mononuclear, polygonal

or fusiform with granular protoplasm and a nucleus round or oval in shape also elements polynuclear and gigantic with a hyperchromatic nucleus and a granular homogeneous protoplasm, and elements both mononuclear and polynuclear and with a fibrillar protoplasm. These elements are distributed sparsely or in colonies and with a quantitative variation more accentuated in the fourth, fifth, eighth, and ninth months of pregnancy, they are not influenced by constitutional disorders or diseases of the uterus and adnexa and retrogress and disappear 2 weeks after delivery or after interruption of pregnancy. These elements are totally absent in tubal pregnancy. As collateral findings there are trophoblastic elements in the lumen of the vasa of the decidua and myometrium; these are more prevalent in cases of tubal pregnancy. In postabortive and postpartum retention of ovular residue, these elements persist longer than usual in the areas of decidua and myometrium where the retained tissue is attached.

A varied genesis of these elements is suggested by their characteristics of structure quantitative proportions and topographic ubiquity. The mononuclear forms seem to originate from cytotrophoblastic elements although it has been suggested that such elements can originate also from the cells of Langhans; the polynuclear and mononuclear types with a fibrillary protoplasm must originate from muscular elements, while the polynuclear forms with a clear protoplasm and nuclei defective in chromatin must originate from decidua cells. The author concludes that the cellular elements characteristic of the situs placentaris, with a muscular decidua and connective tissue origin must be understood to be quantitatively and functionally related to the elements of ectodermic origin. Trophoblastic emboli are among the vascular changes found con-

stantly in the placental bed. In eclamptic patients, these are found in the vessels of the uterus as well as in other organs (lungs, liver). The characteristic cellular structure of these embolic formations gives them a trophoblastic origin.

In the ambit of the decidua basalis and myometrial strata of the situs placentaris, the elements of ectodermic origin constantly present are mostly gigantic polynuclears which differ quantitatively in each case according to the stage of pregnancy; also the elements of different origin (muscular, decidua, and connective tissue) which are present are in direct quantitative proportion to the ectodermic components. The definite absence, in the beginning of pregnancy of germinative centers of such ectodermic elements gives them an autonomic property or character later in pregnancy which suggests a functional capacity. However, no hypothesis can be built on the functional activity of such elements. The gigantic mononuclear elements of the situs placentaris are an inherent characteristic of the process of placentation ectodermic in origin, and they vary quantitatively according to the activity of the chorionic ectoderm. This constant quantitative variation noted in the different forms of uterine pathology gives important information in the field of biopsy.

The terms "ectodermal invasion of the uterus" and "chorionic infiltration" must be reserved for special pathological entities. Ectodermal invasion must be reserved for those cases with a quantitative increase of ectodermal elements and a topographic anomalous presence of ectodermal elements in the myometrium. Chorionic infiltration suggests the penetration of chorionic cells within the venous sinuses of the myometrium as well as the lesions resulting from this endovascular anomalous invasion.

JOSÉPH M. A. PARR, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

The Possibility of Surgical Treatment of Anuria
(*Le possibilità della terapia chirurgica dell'anuria*)
G. PRACAROPULO and C. ORIOCCIA. *Boll. Mem.
Soc. piemontese chir.*, 1947 17 247

Surgical treatment of anuria has at times been widely practiced, but in the last few years a reduction in the number of cases has been noticed in the literature.

With the increase in the incidence of anuria since the advent of widespread transfusion and sulfonamide therapy surgical treatment of this condition becomes a topic of renewed interest. After reviewing the results of operative treatment of anuria the author discusses the treatment given at the Surgical Clinic of Torino.

Surgical treatment of anuria consists of the following operations: decapsulation, nephrostomy, pyelotomy, ureterotomy, renal enervation and decortication of the renal artery. The following minor surgical procedures are also used: vesical distention, ureteral catheterization, anesthetic infiltration of the renal pedicle, anesthetic infiltration of the splanchnic nerves, spinal anesthesia and paravertebral nerve block.

Anuria, in a certain sense is always secretory for it always consists in an arrest of the secretory function.

The author follows this classification of anuria: (1) prerenal which is due to causes acting on the circulatory, humoral, or nervous mechanism independent of a primary change in the kidneys themselves; (2) renal due to inflammatory or degenerative processes which affect diffusely the renal parenchyma; (3) subrenal or postrenal caused by obstruction of the ureters or ureter in case of the existence of only one kidney; (4) arenal which occurs when one kidney is absent or severely damaged and the other is totally insufficient; and (5) reflex, which results when inhibitory nervous reflexes arise.

The mechanism by which the various surgical procedures act is discussed in detail.

Indications for surgical treatment of anuria are: 1. Prerenal anuria. The causes of this type of anuria which lie outside the urinary apparatus, include spasm, compression or obliteration of the renal vessels, anuria due to hypotension, hypertension with renal ptosis, and to changes in the blood, e.g. that due to asphyxia. Medical treatment of these conditions is usually very efficient. Minor surgical procedures, e.g. anesthetic infiltration of the renal pedicle or splanchnic nerves to relieve the spasm of the renal vessels, sometimes have to be employed.

2. Renal anuria. The transitory type of renal anuria which follows renal colic and operations, and lasts for from 12 to 24 hours without complications

is treated medically. In acute diffuse glomerular nephritis medical treatment is also efficacious. In the more serious cases decapsulation has been used with benefit. Treatment of chronic nephritis is medical, and that of renal damage resulting from poisoning by heavy metals in the majority of cases is also medical. In these cases decapsulation is of benefit only when done early before irreparable damage has been done to the renal parenchyma.

3. Postrenal anuria due to mechanical obstruction, either intrinsic or extrinsic, is best treated by the proper surgical treatment. In cases of intrinsic obstruction due to calculi, blood or tumors in the urinary system, relief is obtained by the surgical procedure indicated, e.g. ureteral catheterization, nephrostomy or pyelotomy. In cases due to extrinsic obstruction, e.g. pressure of tumors outside of the urinary system, surgical removal is the proper procedure.

4. Reflex anuria usually responds to minor surgical procedures.

Any surgical procedure which is indicated should be done early.

The routine treatment followed by the surgeons of the Surgical Clinic of Torino is given. During the first day or two of anuria, medical treatment is given. If the anuria persists for the second and third day, then minor surgical procedures are employed. If it persists for 4 days, or at most for 5 days, and the patient's general condition is satisfactory, then the proper major surgical procedure indicated in the case at hand is carried out.

In cases of acute nephropathy decapsulation gives good results in most cases. Nephrostomy in others. Surgical intervention is carried out on one side only. The temporary action of decapsulation and nephrostomy does not weaken their application because the treatment carries the patient over the acute episode and temporary relief favors permanent relief. The authors do not think surgery is of any use in cases in which the damage to the renal parenchyma is severe, which is indicated by complete anuria of several days' duration.

The authors have had no experience with the treatment of posttransfusion anuria but they give the results of French authors who have recorded many cases relieved by decapsulation and paravertebral anesthesia.

The authors have treated sulfonamide anuria successfully by medication in most cases. Rarely have they had to resort to minor surgical procedures such as infiltration of the renal pedicle.

Postrenal anuria is treated medically, only the exceptional case requiring relief by bilateral ureteral catheterization or nephrostomy.

In reflex anuria, decapsulation has been done with good results in many cases. The majority of these cases can be treated successfully by medical treat-

ment or minor surgical procedures. Nephrostomy, when used, affords the advantage of exploration of the organ at the time of operation.

BLACKWELL MARKHAM, M.D.

Hematuria from Aneurysm of an Arciform Artery of the Kidney (*Ematuria da aneurisma di un'arteria arciforme del rene*) ANGELO MARINI. *Boll. Mem. Soc. piem. sc. let.* 947 7 313

The cause of hematuria of renal origin can in most cases be determined very easily by modern diagnostic methods. The comparatively few remaining obscure cases of hematuria, so-called essential hematuria, can be treated successfully in 50 per cent of the cases (according to some authors) by simple renal enervation or decapsulation, exploratory nephrotomy and nephrectomy being required in the remaining cases.

A case of renal hematuria of obscure origin studied at the Institute of Urology and Pathological Anatomy at the University of Milan is presented and discussed.

A 61 year old male entered the hospital for the relief of renal colic. Light days before he had wrenched his right flank while riding a bicycle. Later he developed pain in his right flank and passed bloody urine which contained clots over a period of 12 hours. Four days later the same events recurred. On entry physical examination was negative except for gross hematuria. Cystoscopy showed the right ureteral papilla to be plugged by a blood clot. On removal of a 5 cm. clot from the right ureter catheterization was performed and bloody urine was obtained from the right renal pelvis. Pyeloureterography was negative. Intravenous injections of vitamin C were given in an effort to arrest the hematuria, but they were ineffective. An exploratory operation was then resorted to and decapsulation of the right kidney was done. Postoperatively the hematuria returned and persisted. Twenty-eight days after the first operation, a second operation was performed at which time a nephrectomy was done. Histological examination of the kidney removed revealed that the hematuria was due to the presence of a small aneurysm of an arciform artery of the right kidney.

This case is reported as an example of the impossibility of making an accurate preoperative diagnosis in cases of essential hematuria. After the ordinary diagnostic procedures had failed to reveal the cause, even a nephrotomy failed to give additional information. Arteriography is perhaps the only method which would have thrown any light on the diagnosis and this is doubtful.

The author concludes that in cases of essential hematuria which are unaffected by all possible methods of medical treatment, surgical treatment should be employed promptly. Renal decapsulation should first be tried. Nephrotomy with removal of tissue for biopsy should be done in cases in which the exposed kidney suggests pathology of the renal parenchyma. When the hematuria persists in spite of these measures, radical nephrectomy should be

done to eliminate the danger of a neoplasm which cannot be diagnosed macroscopically.

BLACKWELL MARKHAM, M.D.

Chronic Pyelonephritis. J. H. CARVER. *Bull. Urol.* 947 9 35.

Chronic pyelonephritis is a serious disease, leading to the progressive destruction of the renal parenchyma. It is accompanied by hypertension in about 30 per cent of the cases. The disease may be unilateral or bilateral. The pelvis of the kidney is widened, the calices are clubbed, and the kidney may be reduced to half its normal size because of contraction. These changes are best seen in the retrograde pyelogram. The author reports 6 cases. He has usually found the organism to be the *Bacillus coli*, the *Staphylococcus*, or the *Streptococcus*. The symptoms are rather insidious and varied. There may be recurring attacks of pain in the loin, with frequency and burning. Repeated chills and fever are not uncommon. Most patients complain of lassitude, inertia, and the constant feeling of being below par.

The diagnosis may be difficult. Urinalysis usually shows low concentration, albumin, a few red blood cells, pus cells, and organisms on culture. Pyelography in the early stages of the disease may fail to show more than widening of one or two calices. Intravenous urography will likely demonstrate poor function. The blood urea is often elevated.

The author suggests that the term pyelitis be discarded as it does not reveal the true seriousness of the disease.

JOSEPH E. MAYER, M.D.

Contribution to the Study of Primitive Papillary Tumors of the Renal Pelvis (*Contributo allo studio dei tumori primitivi papillari del bacinetto renale*). FERNANDO TOROCCI. *Arch. ital. urol.* 1947 27 20.

A 39 year old fisherman upon returning from heavy labor noted that his urine was of a reddish-brown color and experienced vague pains in the region of the left flank, with pollakiuria and steady pain in the region of the bladder more intense at the end of micturition. At this time a physician diagnosed congestion of the neck of the bladder. During the following 3 months the pains occurred twice. Sixty days after the first attack the bleeding reappeared and was again associated with the symptoms described. This attack finally ended as urinary retention which was relieved by catheterization. Another attack of acute urinary retention led to hospitalization and the patient suffered another attack of hematuria while he was absolutely bedfast and without the slightest provocation.

Laboratory methods, particularly ascending pyelography suggested calculus however the absence of renal colic, febrile attacks, or pyuria, and the unprovoked hematuria favored the diagnosis of neoplasm. The kidney together with the ureter was removed. In the somewhat enlarged kidney pelvis was found a large cauliflower growth attached to the pelvic wall where it was reflected on a renal papilla. In addition there were a number of small papillomas.

tous excrescences scattered about at other points on the pelvic wall.

Histologic examination of these growths disclosed the characteristic stromal arborizations covered by the multiple layers of predominantly cylindrical epithelial cells resembling the normal mucosal lining of the renal pelvis. However as the basal zones of the tumor were approached the histologic picture indicated a lack of sharp delineation between the epithelial and the underlying stroma the pegs of epithelial proliferation in places penetrating for some distance into the underlying connective tissue which forms the supporting structure.

The author emphasizes in this report the superiority of clinical control over laboratory methods of diagnosis. He also insists on the necessity of ureteronephrectomy in these patients since in many there are secondary or accessory growths within the kidney substance and in the ureter.

JOHN W. BRENNAN, M.D.

Ureteroduodenal Anastomosis. JOSEPH G. FORTNER and JOSEPH H. KIEFER. *J Urol* Balt., 1948 59 51

Because the usual rectosigmoidal site for anastomosis of the ureters into the bowel is not entirely satisfactory the authors undertook an experimental study to clarify and re-examine the possibilities of ureteral implantation into the various portions of the small bowel.

The experiment was divided into 3 parts. In part 1 the ureters were transplanted into the rectosigmoid for the purpose of perfecting a technique and establishing controls which could be compared with the results of further investigation. In part 2 both ureters were transplanted into the duodenum at one operative procedure. In part 3 one ureter was transplanted into the duodenum at 1 operation followed by transplantation of the second ureter at a later date.

The dog was used as the experimental animal. The preoperative care consisted of nothing by mouth, with the exception of water for 36 hours prior to operation. At no time were the sulfonamides penicillin streptomycin or similar drugs used. A general diet was given to all dogs both preoperatively and postoperatively. Blood samples were drawn before the operation and every day or every other day thereafter, according to the condition of the dog. Nonprotein nitrogen and urea nitrogen determinations were made on these blood samples. Liver and kidney biopsies were taken at the time of operation. Upon death of the animal an autopsy was done and tissues taken for microscopic study. The anesthetic agents used were morphine sulfate and nembutal given intraperitoneally.

A modified Coffey 1 operation was used. With an anterior abdominal approach the ureter was mobilized from the urinary bladder to the kidney pelvis by opening the posterior parietal peritoneum. A longitudinal incision from 3 to 4 cm. long was made through the serosa and muscularis of the selected portion of the bowel. The distal end of the ureter was then implanted through an opening made through

the bowel mucosa at the distal end of this incision. The distal end of the ureter was transfixed by a suture through the wall of the bowel. The bowel wall was then sutured in two layers over the intramural ureter which completed a submucosal tunnel. The anterior abdominal incision was closed. Care was taken to keep the ureter straight and untwisted also to prevent compression in the submucosal tunnel. The blood supply to the ureter was carefully preserved.

Part 1: A control group of 7 dogs in which rectosigmoidal transplants were done. After completion of the study it was concluded that an anastomosis which would permit the operated animal to live a prolonged period of time had been made in all but 2 cases. Although some of the other animals showed evidence of hydronephrosis pyonephrosis or pyelonephritis, these continued clinically normal, and chemically demonstrated from slight to moderate elevation of their nonprotein nitrogen and urea nitrogen levels. Other anastomoses were entirely satisfactory.

Part 2: The second group (with bilateral implantation into the duodenum at 1 stage) included 14 dogs. Six of these animals died on the second and third postoperative days of factors which were not relevant to the experiment. The remaining 8 animals followed a singular similar course clinically chemically and pathologically. These animals lived from 5 to 12 days following the operative procedure. Clinically they differed only by being progressively less active than in their preoperative state. They did not eat or drink well postoperatively and demonstrated marked cachexia 2 or 3 days before death. Chemically there was an astounding rise in the nonprotein nitrogen and urea nitrogen on the first postoperative day. Following this there was a rapid rise in both values in an almost parallel fashion.

From this group it was concluded that bilateral transplantation of the ureter into the duodenum is surgically possible, but the animal's longevity is limited by factors to be discussed later.

Part 3: In this group (unilateral transplant into the duodenum at 1 stage followed by transplantation of the opposite ureter into the duodenum about 2 months later) 4 animals were used 2 of which lived 7 days. The remaining 2 were in such poor condition on the fifth postoperative day that they were sacrificed. The nonprotein nitrogen and urea nitrogen in the 2 surviving animals rose slightly, yet remained within normal limits during the first few days. Following the second stage procedure there was little or no difference from the animals in group 2 and the authors concluded that transplantation of the ureters into the duodenum in 2 stages does not give the animals a tolerance to a high nonprotein nitrogen and its consequent deleterious effects. The hydronephrosis encountered is evidence that the kidney continues to function more or less well in its new relationship.

The course of the animals with bilateral ureteroduodenostomy is such that two entirely different

service often 2 or 3 months after the cystostomy operation. In these cases the lumen of the urethra was not only obliterated but the proximal and distal urethral cul-de-sacs were often separated by several centimeters of dense cicatricial tissue often extending for considerable distances in various directions. In some instances previous reconstructive operations had been attempted and in others fistulous tracts purulent pockets and abscesses had to be given preliminary operative attention.

In many of these cases the roentgen films and even the case histories were lost so that in much the author has had to depend upon his memory however at least some detail is given in 26 cases. These included 9 cases observed before he developed his method of simultaneous ascending and retrograde urethrography and 17 observed after the method was developed. In the latter group there were 9 cases with extensive cicatricial destruction of the urethral lumen, 1 case with a moderate amount of destruction and 1 with a very small connective tissue block. Three cases were complicated by the presence of abscesses and in 2 cases the two ends of the urethra were displaced with reference to one another.

The operative procedure described is that used for the extensive injury with as much as 3 cm. of sclerotic tissue which blocks off the two ends of the urethra. When the patient is ready for operation that is, when any infectious processes are cleared up as well as possible the connective tissue is approached through the usual midline perineal incision the anobulbar ligament and the rectourethral muscle being cut to open up the prostaticorectal space. An incision is made into the urethral lumen including that of the bulb and distal cul-de-sac and a catheter is retained in the closed distal sac of the urethra by an assistant acting as a guide. The retrograde catheter, also held firmly in the proximal sac, is palpated and the incision is carried backward being kept well forward, away from the rectum, so as to open up this part of the urethra also. The 2 ends of the urethra are then freshened and all the sclerotic connective tissue is cut away as thoroughly as possible even laterally as far as possible into healthy tissues. The in-lying rubber tube is then introduced in retrograde direction through the bladder and proximal urethral opening into the operative wound and thence through the distal portion of the urethra so as to protrude through both the cystostomy opening into the abdomen and through the external urethral meatus. Apparently no attempt is made to unite the two ends of the urethra and the membranous urethra is closed by any tissue which may be available around the rubber tube. In case of necessity even the anterior wall of the rectum may be used to fill out the defect. The incision in the bulbous portion of the urethra is then closed with great precision by means of small catgut sutures in several layers.

The postoperative care of the patient is at least as important as the operation itself. The in-lying rubber tube is retained in place for 25 days or longer, and it is kept covered with an antiseptic paste. If

signs of infection appear the tube (even though it become exposed in places) is not disturbed nor is any attempt made to cover it over with additional sutures as reconstruction of the urethral lumen is left to the natural proliferative processes of the tissues. If one or two sutures should show a little pus those sutures are removed but the others remain undisturbed. Constipation is induced for 7 or 8 days following the operation. However the dressings are changed daily even before the bowel is permitted to move. The in-lying tube is flushed out daily and kept sterile. In a few of the latest cases penicillin had become available and seemed to be of striking benefit.

All of the patients in this material were cured by this method. A few complained of some incontinence of urine and 2 experienced periods of acute urinary retention however this difficulty could always be relieved by passing a sound and the condition was much relieved by diathermy treatments with a metal sound as electrode. The author believes that the retention resulted from urethral spasm.

GENITAL ORGANS

A Study on the Subject of Occult Cancer of the Prostate (Investigación sobre el cáncer oculto de la próstata) JORGE E. LUZZI. *Rev. méd. Rosario* 1947 37 845

In the year from November 1943 to November 1944 the author procured 141 prostate glands from autopsies on males without discrimination as to age. This study was carried out at the Institute of Anatomy and Pathologic Physiology in Rosario.

These specimens were so prepared and sectioned as never to leave more than 4 mm. of thickness without microscopic study. The stain used was hematoxylin-eosine. In this series cancer was found histologically in only 3 glands (2 per cent). However all of these cancers occurred in patients over 40 years of age of whom there were 112. Two of these cancers of the prostate were by no means occult but could have been diagnosed clinically. In fact one of the patients died of metastases to the liver. Considering therefore that 1 case of occult cancer was found among 112 patients over 40 years of age the corrected figure of incidence would be 1.2 per cent, and for the entire number of 141 prostates from patients of all ages and fairly representative of the general population the incidence would be 0.7 per cent.

These figures are a far cry from the disquieting reports of high percentages of occult cancer of the prostate from other sources and the author, in an attempt to elucidate in every way possible the discrepancies thus introduced into the literature gives three possible sources of varying interpretations. The first is the case of the prostate which has already begun to develop the typical adenoma which in turn compresses the neighboring tissues collapses and distorts the glandular tubules and at times converts them into a mere trabecular strip of cells of irregular

size and shape. Another source of conflicting interpretation of the histologic picture might occur in the cases of senile prostates in which the normal processes may alter not only the form and disposition of the cellular elements but also the staining characteristics, and present on occasion a histologic picture very difficult to differentiate from that of incipient neoplasm. The final cause of confusion which the author has encountered may lie in the existence in the same prostatic matrix of a different types of glandular tubules. One type of tubules has cells of basophilic plasma and a compressed appearance with a tiny glandular lumen or no lumen at all, the cells themselves exhibiting meager amounts of plasma and a large deeply staining nucleus. The tubules are irregularly disposed and in general give the impression of a pseudoneoplastic process. The other type is composed of tubules whose cell-protoplasm may in contradistinction to the first type be designated acidophilic. These tubules form glandular mosaics lying closely side by side, almost without interstitial connective tissue. The lumina of these tubules are larger than those in the first type and contain rather small varying amounts of secretion. The cells composing these glandular structures are large clear and rather regularly arranged, with abundant protoplasm and lightly staining basally situated nuclei. These areas are interpreted by the author as possible beginnings of adenomatous prostatic hypertrophy with different types of histologic pictures because of the differing degrees of maturation of the component cells. All these findings he designates as pseudoneoplastic histologic manifestations.

JOHN W. BRECKMAN M.D.

The Medico-surgical Treatment of Cancer of the Prostate. Subcapsular Orchiectomy and Hormone Therapy (Sur le traitement médico-chirurgical d' cancer de la prostate. Orchiectomie sous-capulaire et hormonothérapie) AUGUSTE CASUTO. *J. urol. méd.,* Par. 946-47 53 435.

This eminent urologist from Rome, Italy begins his address by expressing his appreciation of the courtesy shown him by the allied army of occupation and especially by Lieutenant Colonel DISANZANO, chief of the sanitary service of the Army of the United States in Rome in providing him with medical literature and with such quantities of diethylstilbestrol gratis as he has needed for his work.

Since the opinions of writers do not agree as to the preferred treatment of cancer of the prostate the author feels no hesitancy in stating his own opinion although he has not been using his methods for a 5 year period as yet. He prefers immediate castration by subcapsular curettement of the glandular tissues of the testicle as proposed by Riiba in 1942. Medical treatment with diethylstilbestrol is then initiated and continued for long periods of time. The usual dose of this preparation is 5 mgm. per day orally however the dosage is increased or diminished as indicated for the individual case. Some patients have tolerated as much as 1,000 mgm. of

diethylstilbestrol daily. When the castration has preceded the medical treatment no effects are noted on the breasts or general condition. If the patient proves to be intolerant to the diethylstilbestrol the dosage may be lowered or another preparation such as dienestrol may be substituted.

Of course if the patient refuses the operation, medical treatment is all that remains however in these cases the effects are pretty much the same although not so soon attained and not so pronounced. The most striking effects aside from the prolongation of life is the relief from incontinence and retention, and from pain. The tumor becomes softer and loses its rough nodular feel and even seems to decrease in size however the author has never seen the tumor disappear entirely. The pains ascribable to the metastases appear also to be relieved.

This is the first report of a chemical preparation which exerts an effect on cancer and this fact alone should spur research in this field.

JOHN W. BRECKMAN M.D.

Aseptic Prostatectomy FRANCIS E. STOCK. *Br. J. Urol.* 947 9 306.

The method of prostatectomy originated by Wilson Hey is discussed and 24 cases in which this technique was used are reported. The author stresses that the diagnosis must be a clinical one, and that the patients must not be subjected to cystoscopy or catheterization before operation. If the patient is seen in a state of acute retention, the operation is performed as an emergency. The technique is described in detail.

After the bladder has been opened and emptied suprapubically a catheter is passed in retrograde fashion. The ureters are identified and a mark made with the diathermy knife $\frac{1}{4}$ inch in front of each. From these marks a diathermy incision through the mucosa is made around the periphery of the upper surface of the prostate. Enucleation of the adenoma is then done, bleeding points being grasped and fulgurated as they are encountered. A V-shaped piece of the trigone is then removed, the apex of the V being posterior. A urethral catheter is then placed by "railroading" it through in a retrograde manner and fixed in the bladder by a Harris stitch. The bladder is closed in two layers, and tested for water tight integrity. A drain is left in the space of Retzius.

The catheter was removed on the third or fourth postoperative day and the drain from the space of Retzius on the second. Early ambulation as routine, as was chemotherapy.

The author's conclusions were favorable. There was no mortality. JOSEPH E. MAURER, M.D.

Retropubic Extravesical Prostatectomy of Millin (Die retropubische extravesikale Prostatektomie nach Millin) W. BAURMANN, *Helvet. chir. acts* 1947 14 370.

The author reports on 50 cases of prostatectomy by Millin's method. His series of cases is classified

Fig 1 (Stock) a, Lateral lobes delivered into bladder. The floor of the urethra is divided with a diathermy cut at about the point where it dips out of sight. b, Excision of trigone with diathermy. c, Appearance of prostatic cavity after trigonectomy and incision of interureteric bar. d, Fixation of urethral tube and insertion of continuous catgut suture avoiding mucous membrane. e, Interrupted nylon sutures in one or two layers.

as follows: adenomatous prostatic hypertrophy (soft form) 28, fibrous solid form of prostatic hypertrophy, 9, prostatic hypertrophy with chronic interstitial inflammation 7, sphincter sclerosing or prostatic atrophy 3, and carcinomatous degeneration in prostatic hypertrophy 4. Millin's operation is described and the postoperative care is outlined. The postoperative course is particularly favorable, morphine seldom being required. Operative shock is slight and approximates that of perineal prostatectomy. The prevesical drain is removed about the third or fourth day and the catheter the sixth day.

Total urinary incontinence did not occur while relative incontinence with coughing and straining occurred once in a few weeks and twice in a few months. Urinary retention immediately or soon after operation occurred in 6 patients of whom 3 were among the first patients operated upon. As a rule in 1 to 3 days the urine was no longer bloody and postoperative bleeding in general was slight. Late bleeding occurred in 4 cases but was never serious. A slight wound infection without urinary fistula occurred in 2 cases and healed spontaneously. A transient urinary fistula was observed in 3 patients. Persistent urinary fistula was observed twice and was the most serious wound complication noted. Other complications were pyelitis 2 cases, pulmonary infarct, 1 case, and bronchopneumonia, 1 case.

There were only 2 deaths in the series in which the prostatectomy could be considered contributory, one occurring 5 weeks postoperatively from acute hem-

orrhage from a duodenal ulcer and the other after 7 weeks from liver insufficiency.

Sexual potency is not impaired as frequently following Millin's operation as after perineal prostatectomy. Millin's operation has 2 disadvantages, namely the danger of urinary fistula and of infection of the space of Retzius. These can be minimized by avoiding injury to the capsule with the diathermy needle.

JOHN L. LINDQUIST, M.D.

Oxidized Cellulose in Suprapubic Prostatectomy

GEORGE D. STUMP and ROBERT C. THUMANN, JR.
J. Urol. Balt. 1948, 59, 102

Primary closure of the suprapubic wound following prostatectomy is not new, but it has never become a widespread or common procedure because of the frequent occurrence of postoperative hemorrhage.

By using the Foley bag catheter and oxidized cellulose, the authors wish to present a method of primary closure which is relatively simple and gives minimal postoperative bleeding. Hospital days are reduced as compared with other forms of suprapubic approaches; there is no urine spilling over the abdomen and the postoperative course by comparison is much more comfortable. The procedure follows:

1. The bladder incision is kept high in the dome with little prevessel and prevessel dissection.

2. After the prostate is enucleated, immediate hemorrhage is controlled by a hot pack held in the fossa for 5 minutes.

3. A 30 c.c. Foley bag is adequate for most cases.

4. Oxidized cellulose is placed smoothly around the Foley bulb.

5. The bag and gauze should be large enough to fold the vesical neck into the prostatic fossa.

6. There may be some bleeding along the course of the urethra, but this does not interfere with the function of the catheter and is not cause for alarm.

7. The bladder is closed completely in 3 layers.

8. Oxidized gauze begins to wash out on the operating room table and is usually all out within 72 hours.

9. The catheter is removed by the sixth or seventh postoperative day and the patient allowed to void.

10. If the catheter does not drain well, it may be replaced at any time.

A total of 15 primary closures with oxidized cellulose have been performed at Harper Hospital, Detroit. Eleven cases of uncomplicated benign hyperplasia of the prostate are presented. The other 4 cases presented complicating features which will be mentioned later.

In all of the 15 cases immediate postoperative bleeding was a minimum. In 1 of the 11 cases, the suprapubic wound reopened and urine drained out upon removal of the catheter. This was attributed to a low incision in the bladder at the operation which tore into the vesical neck during the enucleation and read closure of the bladder difficult and in adequate for primary closure.

In 1 other case in which removal of the catheter was anticipated on the ninth postoperative day the patient bled from the prostatic bed the night previous which necessitated delay in removal of the catheter.

In all but 2 cases, the urethral catheter was removed between the sixth and eighth days. The patients voided freely and maintained a solid suprapubic wound.

In 1 patient cystoscopy was done on the tenth postoperative day. No oxidized cellulose was present and epithelization had begun.

In 1 of the 4 cases not included in the series the pathological report was adenocarcinoma, although the preoperative diagnosis was benign hyperplasia of the prostate. In view of this, an indwelling catheter was left in 13 days as delayed healing was anticipated. The patient went home voiding freely with a solid suprapubic wound on the fifteenth postoperative day.

Another patient with a complicating urethrocutaneous fistula at the penoscrotal junction maintained an indwelling catheter for 10 days and went home voiding freely with a solid fistulous tract and suprapubic wound on the fourteenth day. The pathological report was leiomyofibroma of the prostate.

The third case is mentioned to show the complications which follow the placing of the Foley bulb in the prostatic fossa itself. The postoperative course was beset with severe bladder spasm and incontinence because a discouraging feature after removal of the catheter on the eighth day. Damage to the external sphincter had occurred from the inflated and tightly drawn Foley bulb. However the supra-

pubic wound remained closed in spite of the complications. Care must be taken in the proper placement of the Foley bulb.

The last case was that of a 74 year old man, which was complicated by severe atherosclerotic damage to the myocardium and auricular fibrillation. By the time of surgery the cardiac condition had been controlled with digitalis. Postoperatively the patient had clouding of consciousness for 12 days. The catheter was removed on the eighth day but because of the mental state, involuntary micturition, and peristent urine it was re-inserted until the sixteenth day after which the patient voided freely and maintained a solid suprapubic wound. Because of the cardiac and general status the convalescence was prolonged, the patient leaving the hospital on the thirty-fourth postoperative day.

JOHN A. LOHR M.D.

Spontaneous Gangrene of the Scrotum. L. T. BARCLAY *Plast. Reconstr. Surg.* 94:3:56.

Spontaneous gangrene of the scrotum first reported by Fournier in 1854 presents the following salient features:

1. Sudden onset in an otherwise healthy male.
2. Rapid progression of the gangrene.
3. Total absence of the normal causes of gangrene.

Beside these three clinical features the majority of cases present other common factors, as follows:

1. Extensive and relatively constant areas of gangrene. The testes, spermatic cord, and inguinal regions are rarely affected. Involvement of the penis, especially in the region of the scrotopenile fold, is not common.

2. A tendency for spontaneous repair to occur. Manson believes that in most cases there are three triangular flaps of skin left at the margins of and projecting into the area of slough. Two of the flaps are based laterally one based posteriorly. Between these flaps lie both testicles. These flaps serve as centers from which epithelization begins. The repair appears rather to be due to contraction of new scar tissue which draws the remaining scrotum over the testes, than to the epithelium growing over the granulations from the periphery.

The etiology remains obscure, but two theories have been advanced to explain the onset of this condition. A fulminating erysipelas is the cause favored by the French authors, but this theory does not explain either those cases in which the infection is not due to the hemolytic streptococcus or those cases that arise spontaneously in otherwise normal males. A second theory suggests that the disease is a gas gangrene due to either the *Bacillus welchii* or other anaerobes.

Manson offers an alternative explanation. He believes that the condition is a vascular disaster of infective origin, analogous to cavernous sinus thrombosis. The infection does not have any specificity other than the presence of a pathogenic organism which causes rapid thrombosis in the area supplied by these vessels. The blood supply to this region accounts for the constant area of slough, and also for

the presence of the three flaps. This area is supplied by the external branch of the femoral artery and the superficial perineal arteries. The limitation of slough on the under surface of the penis is due to the fact that the dorsal vessels remain intact having no connection with the veins of the mediastinum below the urogenital diaphragm. The high mortality and the profound illness of these patients suggests more than localized gangrene of the scrotum due to vascular occlusion. It would seem that a combination of factors are responsible for the onset of this condition.

The treatment of choice is the radical removal of the necrotic area for this procedure provides free drainage and helps to speed recovery. Surgical repair by skin graft is considered unnecessary.

The author reported a case in which a patient 44 years of age had been entirely well prior to the spontaneous onset of his illness. He was hospitalized in an acutely ill condition. The admission diagnosis was spontaneous gangrene of the scrotum with associated deep thrombophlebitis of the left leg and infarction of the lower lobe of the right lung. The treatment consisted of tulle gras dressings to the scrotum. Eusol in gauze dressings were renewed twice a day. Chemotherapy consisted of penicillin (14,000 units every 3 hours) and adequate doses of sulfadiazine by mouth. Dicumarol (200 mgm.) was given on admission and 100 mgm. were given daily under control by daily prothrombin estimations. A full diet and 3,000 c.c. of fluid were given each day. Healing was rapid under this regime, and on the twenty-eighth day the patient was discharged in good condition. *CONRAD A. KUEHN MD*

MISCELLANEOUS

Reiter's Syndrome. ALBERT A. CREECH and FRANK S. BEAZLEY, JR. *J. Urol.* Balt., 1948 59 234.

In 1916 Hand Reiter, while perhaps not the first to see was first to describe a clinical syndrome characterized by urethritis, conjunctivitis and arthritis which was nongonorrheal in nature.

Since Reiter's original description 152 cases have been reported in the literature to our knowledge.

All the cases reported in the literature have occurred in young males (the youngest 16 the oldest 42), with the exception of 1 case reported by Lever and Crawford which occurred in a female but about which there was doubt as to its proper classification. Recurrences are seen in about 25 per cent of all cases at intervals of months to years. Multiple recurrences are not uncommon.

The disease process is acute in onset with its manifestations appearing promptly and tending to increase in severity in the first 4 weeks. It is usually ushered in with urethritis or arthritis followed by conjunctivitis, but the manifestations often supercede or superimpose one another and have no constant relationship. In some cases transient diarrhea, cutaneous lesions or ocular symptoms have ushered in the disease. In over 95 per cent of the cases no venereal history or history of sexual exposure within

a significant interval has been obtained. The urethritis and conjunctivitis have been purulent and tend to clear up in a relatively short period of time. The arthritis which is the most persistent and disabling manifestation is usually polyarticular but cases of monoarticular involvement have been reported. In addition to the cardinal triad and complications described by Reiter many other features have been described including interitis, keratitis with peripheral ulceration, balanitis circinata, prostatitis, prostatic abscesses, vesiculitis, hemorrhagic cystitis, dilation of the ureters and renal pelvis, pyelonephritis, joint effusions, and purpura and vesicular cutaneous lesions.

The clinical course of the disease is protracted but self limited attacks varying in severity and lasting from 1 to 3 months with gradual complete recovery, leaving few or no residual symptoms. No form of specific therapy including arsenicals, urotropin, local antiseptics, sulfonamides, penicillin or gold salts has appreciably affected the course of the attacks. Beigebock used arthigen, a vaccine producing a foreign protein reaction in many of his 10 cases with good results. Others have reported favorable responses to fever therapy.

At the present time complete bed rest with symptomatic and supportive therapy is our best treatment.

The laboratory data are not diagnostic. There is usually a moderate leucocytosis of from 10,000 to 20,000, the sedimentation rate is rapid during the active phase returning to normal with recovery. A moderate anemia is usually present, the urine contains pus, the prostatic secretion often contains pus and the synovial fluid is purulent, but sterile.

The most consistent x ray findings have been ill defined osteoporosis with occasional evidence of periosteal proliferation and narrowing of the joint space but this has not been constant.

Various etiologic agents have been suggested as the cause of the disease, including a spirochete, a staphylococcus, an enterotoxin, a filtrable virus and L-pleuropneumonia-like organisms. However smears and cultures of material from the urethra, conjunctiva, prostate, joints and cutaneous lesions have failed to demonstrate the gonococcus or other specific etiologic agent. Also blood and urine cultures, scrapings of the urethra and conjunctiva for inclusion bodies, darkfield studies of penile and mucocutaneous lesions, serologic tests, gonococcal complement fixation tests, agglutinations, animal inoculation, atox examinations and cultures, cold agglutination and fragility tests and Frei-Ducrey tuberculin and allergic skin tests have failed to substantiate or demonstrate a specific type of etiologic agent.

To our knowledge there has been no mention in the literature as to the possible role of foci of infection in Reiter's syndrome. We believe that the presentation of our 2 cases is of value from this standpoint in view of the events following the removal of a focus of infection in each case.

A 37 year old Jewish merchant was first seen with a history of urinary frequency burning on voiding, and a urethral discharge of 1 week's duration. He also complained of pain in the left shoulder which had been present for the same length of time, but had noted no swelling or limitation of motion. No other physical findings were abnormal except for a purulent urethral discharge and a soft, slightly tender and enlarged prostate. A smear of the urethral discharge showed numerous pus cells. The patient returned again 10 days later by which time mild bilateral conjunctivitis had developed in addition to his other symptoms which had not improved in the interval.

Laboratory examination revealed a trace of albumin and a few leucocytes in the urine. Other laboratory examinations were essentially negative.

While his symptoms were distressing the disease process itself was relatively mild. During his hospital stay the temperature did not go above 99.6°F. Codeine and aspirin sufficed to control the pain. He was given a total of 420,000 units of penicillin and was discharged in a much improved condition with only a slight urethral discharge after a 4 day hospital stay.

Two days after discharge, pain developed in the left knee and the pain recurred in his left shoulder. These pains were especially severe at night and kept him from sleeping. His urethral discharge also persisted although not so profuse as previously. Four days later he had a tooth extracted because of an apical abscess. The following day, the left knee became more painful and swollen and he was unable to bear weight upon it and at the same time he developed a moderately severe conjunctivitis. His symptoms became more severe in the following 3 days and he had a chill on October 5, 1945 following which he was readmitted to the hospital.

He was again placed on penicillin (20,000 units q. 3 hrs. for 33 doses) given codeine and aspirin for pain and moist heat was applied to the knee. The conjunctivitis subsided without therapy and gradually the swelling of the knee disappeared without aspiration.

He has remained asymptomatic up until the present (15 months later).

An 18 year old single white male blacksmith from a rural community entered the hospital with a history of having been well until a weeks before entry when he suddenly began passing blood in his urine and began experiencing chilly sensations and fever. He had urinary frequency every hour and burning on voiding. Shortly after the onset of the urinary symptoms pain developed in the right ankle joint. One week after the onset he noted that he was passing pus from his urethra. The right ankle was now swollen and more painful. At the same time he noticed a redness of both eyes and stated that the lids were swollen and stuck together in the mornings and that there was a whitish discharge from his eyes.

Repeated examinations revealed the urine to be alkaline with a specific gravity of from 1.005 to 1.015, a faint trace of albumin, innumerable leucocytes, and a moderate number of erythrocytes. No casts were found in any examination. Urine cultures were sterile, and smears were negative for any organism. Other laboratory data were essentially negative.

On cystoscopy the bladder urine was found to be grossly hemorrhagic and purulent. The bladder mucosa was intensely inflamed throughout but no active bleeding point was found. The ureteral orifices were normally located and of normal appearance.

While hospitalized, the patient was given adequate doses of sulfadiazine and penicillin without apparent benefit. Sodium salicylate did not relieve the joint symptoms. Sedatives and narcotics controlled the pain. Diathermy helped relieve the joint pain.

Following discharge from the hospital, the patient promptly had severe burning and pain on urination and had a recurrence of the swelling of his right ankle, which led to his second hospital admission.

In an effort to discover the etiology of this patient's disease, the question of a focus of infection was considered. It was believed that the patient had septic tonsils and their removal was advised. This was carried out, following which the patient had marked bilateral conjunctivitis, the dysuria became more marked, urethral discharge more profuse, and the right ankle more swollen, red, hot and tender. The symptoms gradually improved over a period of 3 weeks.

CONDITIONS OF THE BONES, JOINTS, MUSCLES TENDONS ETC.

Calcium, Phosphorus, and Phosphatase as Aids in the Diagnosis of Bone Lesions. EDMUND B FLINK. *Radiology* 1948 50 71

Bone disease may in most instances be recognized by roentgen and clinical examinations. In certain cases correlation of all available data, including laboratory criteria, is necessary for a correct diagnosis. A review of calcium, phosphorus and phosphatase determinations and other procedures as they relate to the diagnosis of diseases of bone is presented.

The serum calcium is composed of two fractions the diffusible calcium and the nondiffusible calcium the latter constituting about 45 per cent of the total is bound to protein. When there is no renal insufficiency or hyperglobulinemia 1 gm. of protein binds approximately 0.75 mgm of calcium. Failure to recognize the protein effect may obscure actual hypercalcemia in hyperparathyroidism, or may lead to the false assumption of hypocalcemia.

The phosphatase activity of the serum is an important index of the osteoblastic activity in bone. Clinically two phosphatases are important the alkaline at a pH between 8.6 and 9.3 and the acid at a pH of 5.0. Hemolysis-free serum should be used for the determinations because of an erythrocyte phosphatase. Because of the large number of conditions in which the serum alkaline phosphatase is elevated the finding must be correlated with other observations. The significance of acid phosphatase is very special and relates only to carcinomatous metastases from the prostate.

Calcium excretion in the urine and feces may lead one to the proper diagnosis. Normally about two-thirds of the calcium is excreted in the feces and one-third in the urine. This ratio changes most markedly in diseases of the parathyroid gland. In hyperparathyroidism, the urine calcium is increased, in hypocalcemic states most of the calcium is excreted in the feces.

Hyperparathyroidism is a disease which may be primary in the glands themselves or secondary to renal changes. Care must be taken in the primary type to discern whether there is a functioning adenoma or general hyperplasia of the glands. Treatment of the primary type is surgical removal of the adenoma or subtotal resection of the hyperplastic glands. Careful investigation of patients with renal calculi and with mild polyuria and polydipsia should be made. An increase in urine calcium and serum studies may reveal a previously undiagnosed case of hyperparathyroidism.

The probability of the development of tetany after removal of a parathyroid adenoma or hyperplastic glands is much greater in patients with high values

for serum alkaline phosphatase than in those with normal levels.

Osteomalacia in this country has been chiefly associated with chronic mild steatorrhea. Investigation of tetany may lead to the diagnosis (confirmed by hypocalcemia and a decrease in urine calcium).

Paget's disease may be associated with acute atrophy of bone with the findings of hypercalcemia, polydipsia, polyuria and renal disturbances. These usually occur during immobilization for treatment of fractures in cases of Paget's disease. Under ordinary circumstances the calcium and phosphorus are normal. The phosphatase may be normal or elevated and depends on the extent of the bone involvement.

In multiple myeloma the serum calcium is often increased but the phosphorus and phosphatase are usually normal. Hyperglobulinemia occurs frequent

TABLE I—DIFFERENTIAL DIAGNOSTIC FEATURES OF DISEASES WITH DISTURBED CALCIUM AND PHOSPHORUS METABOLISM

Condition	Serum			Urine		Feces
	Ca	P	Phosphatase (Alkaline)	Ca	P	Ca

ly as does the finding of Bence Jones protein in the urine. There is usually an increased excretion of calcium in the urine. Bone marrow study is confirmatory.

Osteoporosis associated with hyperthyroidism and the menopause is also discussed. A negative calcium balance may persist until the condition is stabilized. Renal osteodystrophy is discussed.

The differential diagnosis of bone diseases is schematically represented in Table I.

Further discussion of the differential diagnosis and a large bibliography is included in the article.

KEMARIL H. SPONKEL, M.D.

Central Bone Abscesses (Les abcès centraux des os)
L. TAVERNIER, *Lyon chir* 947 4 64

Of the 22 cases here reported with brief case histories, 11 followed osteomyelitis, 5 an old infected fracture and 1 a polyarticular infectious pseudoreumatism. Of the remaining 5 bone abscesses, which were primary in the sense that their cause was not determined, it is quite probable that the search for the etiologic factor may have been insufficient. Therefore a special group of cases of the so-called Brodie abscess has not been made. In fact, these abscesses are not always chronic in their course and often tend to pass over into other forms of bone infection. Nevertheless, the primary abscess shows a number of peculiarities which set it off from the other forms. Its onset is more active and its course is not so prolonged (4 to 6 months from the first attacks of pain until the period of recognition). Its attacks of pain are not so violent and its roentgenographic appearance differs from that of the second ary abscess. This abscess destroys the entire thickness of the bone with the exception of the cortex which is itself often bulged out into a fusiform swelling resembling that of a cyst or benign tumor. However, the primary bone abscess should be easily distinguished since it is much more painful and is apt to be accompanied by fever and edema. The spina ventosa has a much less acute course. It may be more difficult to distinguish this abscess from a fuxtaepiphyseal tuberculous osteitis for the distinction may finally rest upon the examination of the contents of the abscess itself.

The cases of secondary abscess may be divided into those which have developed a fistula, those which have not, those with an articular form which manifests itself as recurrent attacks of chronic arthritis until the condition is cured by the finding and removal of the original abscess in the adjacent bone and finally the abscesses which are secondary to an osteomyelitis healed by penicillin. Six of these 22 abscesses were accompanied by fistula formation all were recurrent, the periods when they were open giving complete relief to symptoms as a rule. In several instances there were present typical findings of abscess in the bone with typical relief of pain from drainage through the fistula, yet upon operation the fistula was found to come from a secondary subperiosteal abscess while the original abscess with-

in the bone did not connect with it. The author especially emphasizes this finding as a possible explanation of some of the diagnostic errors which have occurred in the past. It may explain how one of the patients in this series could have been operated upon 14 times without discovery of the introsseous abscess. Another condition presenting extreme diagnostic difficulty is the postosteomyelitic painful hyperostosis when the roentgenogram does not show the typical shadow defect of the abscess because of the presence of marked eburnation and thickening of the bony cortex, the differentiation between this condition and painful hyperostosis or so-called hyperostosis with neuralgia, postosteomyelitic osteitis may in the absence of operation be simply impossible. In one instance in this material the roentgen technique did not demonstrate an abscess and no abscess was found by extensive trepanation of the bone and careful search yet the pains were not relieved by the operation and 8 days later the patient was reoperated upon, the abscess was located, and evacuation produced immediate relief.

Of course, when in the presence of a fistula the clinical or roentgenographic findings demonstrate the presence of an abscess the treatment is simple, it consists of trepanation of the bone, curettement of the contents of the abscess cavity and reduction of the edges produced by the trepanation to flat sloping surfaces so as to leave a residual shallow depression in the bone which can easily fill in with scar tissue or regenerated bone. In this process much time has been saved by the use of penicillin even in those cases in which the original abscess followed the failure of complete healing of an acute osteomyelitis in spite of the penicillin the drug seems to be just as potent in hastening the healing process following opening of the abscess and it is hoped that the drug will continue to prove capable of shortening the period of convalescence and healing of the bone following evacuation of these abscesses.

JOHN W. BARNHAM, M.D.

Malignant Degeneration of the Osteogenic Exostoses (Dégénérescence maligne des exostoses ostéogéniques) M. GUILLERMET, M. GARNIER, DUBOIS, PÉREZ and A. MAXIMOUT *Lyon chir* 947 4 70

The authors present the case of a 27 year old woman who had suffered from congenital osteogenic disease since earliest childhood (18 months). She was covered with exostoses and these were especially large in the popliteal spaces and on the thorax. One of the masses (in the left groin) had begun to grow rapidly the lower extremity on that side measured 6 to 7 cm. more than that on the other side. This limb was cyanotic, edematous and exhibited marked collateral circulatory development in the calf region and on the outer surface of the thigh. The tumor mass was removed en bloc together with the left superior ramus of the os iliacum which the mass was attached not far from the pubis. The muscles and fascia thus deprived of their attachment were pulled down and attached to the ischiopectic ramus.

Convalescence was uneventful except for an attack of phlebitis which was brought under control by lumbar infiltrations. For 5 months after the operation the patient was perfectly well.

Histologic diagnosis was of a simple enchondroma well encapsulated, without evidence of calcification or of histologic evidence of sarcomatous degeneration.

The authors believe that the chondromas which appear on the basis of osteogenic exostoses harbor a certain degree of malignancy. However they have been able to find not more than 13 authentic examples of this type of malignant degeneration in the literature and they therefore feel compelled to an extreme reserve in their pronouncements. Nevertheless the rapid growth speaks for a malignant tendency and these tumors must be regarded as somber prognostic possibilities. About a third of the patients whose cases have been published obtained a lasting cure although not all of the patients who were treated successfully died of the tumor effects. The age of the patient seems to be of prognostic value; that is the tumor is perhaps a little less formidable in patients under 30 years of age.

Treatment consists entirely of surgical removal of the rapidly growing neoplasm. This removal is done conservatively leaving the amputations and disarticulations for the enormous masses in those cases with local complications demanding more radical procedures.

JOHN W. BREWSTER, M.D.

Cystlike Lesions of the Carpal Bones, Associated with Ununited Fractures, Aseptic Necrosis, and Traumatic Arthritis. A. K. ROBINSON and DALLAS B. PHILLIPS. *J. Bone Surg.* 1948 30-A 151.

The authors report 3 cases of cystlike lesions of the carpal bones, associated with ununited fractures of the navicular bone (2 cases) and with repeated occupational trauma of the wrist and aseptic necrosis of the capitate (1 case). Bunnell describes several cases in his book and attributes the changes to disturbance of the blood supply to the affected bones.

Case histories, roentgenograms, gross and microscopic pathologic changes and discussion are given. Attention is called to the similarity of cysts of the carpal bones to those of the capital femoral epiphysis and their pathogenesis may be assumed to be essentially the same. The carpal cysts bear some resemblance to subcortical cystlike areas in the femoral head and in the acetabulum at the weight bearing region in chronic degenerative arthritis.

In each case sufficient time had elapsed for advanced revascularization and replacement of the necrotic bone. Each case showed histological evidence of aseptic necrosis in the shell of bone about the cyst. Microscopic sections are illustrated showing the principal changes of the necrotic shell of bone: degenerating articular cartilage, creeping substitution of the cortex, fibrous replacement of the central portions of the bone, necrotic spicules of bone and partially calcified fibrous tissue.

Treatment consisted of surgical exploration of the wrists through dorsal incisions with curettage of the

cyst cavities and partial osteotomies of the affected bones. The ununited fractures of the navicular were not disturbed.

Although degenerative arthritis of the radiocarpal joint was demonstrated in each case preoperatively functional results were considered satisfactory.

KENETH H. SPONDEL, M.D.

Late Manifestations of Occult Lumbosacral Spina Bifida (Späterscheinungen bei Spina bifida occulta lumbosacralis). M. ZIEHNER. *Deutscher chir. Acta* 1947 14 461.

The observation of 3 patients with late manifestations of occult lumbosacral spina bifida led the author to conclude that two types of the condition can be distinguished: (1) the urologic form, characterized by a sacral incontinence of mechanical origin and (2) the orthopedic form which produces sensory and neurotrophic disturbances in the lower extremities. Sacral incontinence points to the location of the lesion in the intermediate nuclear zone of the upper portion of the sacral spinal cord between the anterior and posterior horns while a lesion in the posterior horns or posterior roots is responsible for sensory and neurotrophic disturbances.

Adhesions of the spinal cord in the dorsal cleft area of the lumbosacral portion of the spinal column represent the most important pathologic-anatomic findings. The most frequent site of the incomplete fusion is the caudal invagination of the embryonal neural cord and the pars caudalis. In addition to adhesions, intraspinal occult hernias, myelocoele and meningocele resulting from the incomplete fusion may exert pressure on the nerve tissue. Furthermore, the formation of adhesions and proliferations by the fat and connective tissue within the cleft may be responsible for pressure symptoms.

The late complications are due to the stretching of the adherent caudal portion of the spinal cord caused by the longitudinal growth of the spinal column and the spinal canal in contradistinction to the stationary position of the spinal cord or its normal retraction in the cranial direction.

Irreparable lesions of the nerve tissues and their clinical results can be avoided only by an early recognition of the late manifestations of spina bifida and prompt surgical intervention.

JOSEPH K. NARAT, M.D.

Ischemic Necrosis of the Anterior Crural Muscles. GEORGE S. PHALEN. *Ann. Surg.*, 1948 127 113.

Three cases of localized ischemic necrosis of the anterior tibial muscles are presented. Two of these were secondary to traumatic occlusion of the anterior tibial vessels but the etiology in the third case could not be determined. Impairment of the anterior tibial vessels may be of a degree sufficient to produce gangrene of the anterior crural muscles. In the cases which are associated with fracture of the tibia or fibula the anterior tibial vessels may have been damaged irreparably at the time of the original injury even though the fracture may show little com-

minution or displacement and the trauma producing the fracture may have been of a minor character.

Anatomically several factors may enhance the possibility of damage to the anterior tibial vessels in cases of trauma to the leg. The origins of the anterior and posterior tibial arteries are quite rigidly fixed by surrounding structures so that they are subject to injury not only by direct violence but also by force transmitted to the bifurcation of the popliteal artery from other parts of the leg. The anterior tibial artery passes to the front of the leg through a relatively small aperture above the upper border of the interosseous membrane. The vessel might be damaged by any trauma transmitted to this site. At this location, too, the vessel lies close to the medial side of the neck of the fibula and might be traumatized easily by a jagged fragment of bone when the head and neck of the fibula are fractured. Finally the thick deep fascia of the leg, the anterior intermuscular septum, the interosseous membrane and the tibia and fibula rigidly enclose the tibial anterior extensor hallucis longus extensor digitorum longus and peroneus tertius muscles. The anterior tibial vessels and the peroneal nerve enter this compartment and may be secondarily damaged by pressure produced by swelling within this tightly enclosed space.

In one of the author's cases the correct diagnosis became obvious because of the extensive loss of skin overlying the anterior crural compartment. The diagnosis in the 2 other cases however was not made until the anterior crural muscles were explored surgically. In 1 instance 2 months after the onset of symptoms, and in another one month after injury surgical intervention was undertaken. The author indicates that measures directed toward restoration or improvement of the local circulation in the lower leg might prevent or at least reduce the extensive gangrene of muscle tissue. Lumbar sympathetic blocks are valuable in almost any case of arterial spasm. If these are not successful surgical exploration of the anterior tibial vessel should be considered and either periarterial sympathectomy or arteriectomy should be done to improve the collateral circulation. Extensive fasciotomy of the anterior crural fascia may be necessary to relieve the increased pressure within the closed compartment.

The surgeon is cautioned that extreme care must be taken not to introduce any pyogenic organisms since once such organisms have been inoculated into a bed of necrotic muscle (as was done in case 1) the infection cannot be controlled until all the necrotic tissue has been removed.

If the anterior crural muscles have been damaged irreparably tendon transplantation may restore adequate extension to the foot and enable the patient to walk without a brace. Either the posterior tibial muscle alone or preferably this muscle in combination with one of the peroneal muscles, may be used. Arthrodesis of the ankle joint or even arthrodesis of the subtalar joint should not be necessary in a case of this type.

C. FRED GORDON, M.D.

Hypermobia Flatfoot with a Short Tendo Achillis. ROBERT I. HARRIS and THOMAS BEATY. *J Bone Surg* 94B, 30-A, 116.

The purpose of this article is to report certain recent observations regarding flatfoot, and particularly to discuss the relationship between the architecture of the tarsus in severe flatfoot and the impairment of function resulting therefrom.

During 1944 and 1945 the Royal Canadian Army Medical Corps conducted an extensive survey into army foot problems, which included the careful and detailed examination of the feet of 3,600 recruits, with subsequent re-examination. It became evident that pes planus must be divided into at least three varieties: (1) the severe and disabling type discussed in this article; (2) peroneal spastic flatfoot, also gravely incapacitating; and (3) simple depression of the longitudinal arch which is of little consequence as a cause of disability.

Clinical manifestations of hypermobile flatfoot with a short tendo achillis include a history of deformity from childhood. Symptoms usually appear during adolescence and disability increases with age. The feet are flat only on weight bearing. The shortness of the tendo achillis causes limitation of dorsiflexion at the ankle joint. The limitation of dorsiflexion is concealed on casual observation because of the hypermobility of the subtalar and midtarsal joints. Unless the heel is prevented from going into valgus and the forefoot from abduction the actual limitation of dorsiflexion at the ankle joint cannot be determined. There is instability of the subtalar and midtarsal joints.

The characteristics of the deformity are described. The head of the talus is thrust downward and inward the calcaneus is tilted into valgus, and the forepart of the foot is swung outward in relation to the hindfoot.

The incidence of this condition in 3,619 soldiers was 25 with severe deformity and 192 with mild deformity. Peroneal spastic flatfoot was diagnosed in 74 individuals and all other cases of low arch amounted to 524.

The anatomical features were studied in 200 cadavers at the University of Toronto. The conclusion was reached that weak support of the head of the talus is the cause of the deformity. Excellent illustrations are provided to demonstrate this view. Roentgenograms of the feet of 3,619 soldiers confirmed the conclusions regarding the instability of the talus on the calcaneus.

The conception that the function of the foot and its shape under the stress of weight bearing depend chiefly upon the design of the tarsal bones and their position in relation to each other is compared with the hypothesis of active support of the foot by muscle power.

A general plan of treatment is outlined. Conservative care is given in mild and severe cases until late adolescence and maturity. This consists of boot adjustments of an elevated heel, a medial border wedge on both sole and heel, the Whitman support,

and muscle exercises. Activity should be guided within the capacity of the patient. Should reduced activity and conservative measures fail in late adolescence and adulthood surgical arthrodesis of the subtalar and midtarsal joints with the foot in corrected position should be accomplished. Lengthening of the tendo achillis is apparently not deemed necessary or desirable. KENATH H. SPONSEL, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES TENDONS, ETC.

Repair of Major Tendon Ruptures by Buried Removable Suture. HARRISON L. McLAUGHLIN. *Am J Surg* 1947 74 758.

A method of internal fixation for fractured tendons utilizing the removable traction suture principle evolved by Bunnell was carried out in 6 lesions of the quadriceps mechanism and 8 lesions of the tendo achillis. The associated muscle components are among the strongest in the body so that marked retraction of the proximal tendon fragment is the rule and these muscle forces must be overcome and controlled before restoration and maintenance of the anatomy can be accomplished. When the lesion has been present for some weeks or months as is not infrequently the case extensive cicatrization of the whole local area and a relatively fixed contracture of the retracting musculature make the treatment problem still more difficult. In all cases even after surgical repair has been accomplished successfully, the normal functional demand which ambulation places upon the major tendons of the lower extremity has made maintenance of function throughout the healing period difficult to accomplish without seriously jeopardizing the integrity of the suture line. The author stresses that tendon repair requires accurate and snug apposition of healthy to healthy tissue without tension at the repair site with a minimum of foreign material (whether suture material, fascia, or dead tendon fibers) at the healing site and a maximum maintenance of function throughout the healing period.

The technique involved in the repair of the tendo achillis and the repair of the quadriceps mechanism is adequately described.

The wound is closed in layers over the entire fixation apparatus. Both ends of the bolt and the lead shot on the removing wire occupy a relatively subcutaneous position and remain easily palpable. Removal requires a small incision at each of these three palpable points. Local infiltration with procaine hydrochloride provides adequate anesthesia for this purpose. The terminal ends of the main suture are divided and the bolt mechanism is unscrewed and removed through the two distal incisions. The lead shot is then identified by palpation and the remainder of the apparatus withdrawn through the proximal incision by traction on the removing wire.

In the postoperative management of repair operations performed on the quadriceps mechanism the

extremity is put at complete rest for from 48 to 72 hours and then placed in balanced suspension. All joints except the knee are mobilized fully. The knee is mobilized through the arc predetermined at operation.

When the operative wound has healed ambulation with weight bearing is begun with the involved knee protected by an extension splint or brace. The internal fixation apparatus is removed 8 weeks following operation. At the same time all external protection is removed and progressive resumption of normal activities encouraged. As a result of early mobilization followed by subsequent continuous active function the penalties of restricting joint motion by the protective splint or brace are minimized and ambulation is made safe and possible throughout the period required for tendon healing. The results in 4 patients treated by a removable traction suture are tabulated.

In the discussion of this article, Sterling Bunnell described the use of various metal suture materials in such cases. Stainless steel wire for tendon sutures causes the least tissue reaction and tends not to produce adhesions. Tantalum is unfit as it is brittle and rough. After 3 or 4 weeks the suture should be withdrawn as by then the tendon has become physiologically united and any suture material is just an irritating foreign body. A word of caution was inserted concerning the use of the pull-out wire. This should not have a large loop as tissue may grow through it and hinder its withdrawal. To prevent this the loop should be closed, but not too tightly as it may break. If the suture does not withdraw the application of a rubber band will usually lead to delivery of the wire over night.

C. FRED GORRINGE, M.D.

Excision of the Elbow Joint. W. H. KIRKALDY WIL. *118. Lancet* Lond. 1948 1 53.

The author presented case reports on 14 Kenya patients in Nairobi of whom the elbow was resected. This procedure produced a reasonable proportion of useful joints over a 20 year period.

The indications for this operation are given by the author as follows: (1) tuberculosis when excision of the joint removes the focus of disease and gives a full range of painless movement many months before a sound ankylosis could be produced; (2) recent comminuted fractures; (3) old unreduced fracture dislocations; and (4) osteoarthritis following injury to the joint. Postoperatively there should be no more than 10 degrees of limitation of flexion or extension, and in most of the cases there should be a full range of movement. The cases were divided into three groups on the basis of prognosis.

In recent comminuted fractures, old unreduced fractures involving the joint, fracture dislocations, and early cases of tuberculosis, recovery should be rapid and uneventful, and full movement with good lateral stability and good power of the triceps and biceps should be obtained within from 3 to 6 months after the operation. In most cases of tuberculosis re-

covery is slower because of the wasting of the triceps and biceps, and therefore a further 1 or 2 months will elapse before the power in these muscles and the lateral stability of the joint are adequate. In the second group a full range of movement is more easily and rapidly obtained than in the first. The third group includes comminuted fractures around the elbow accompanied by gross injury to another part of the body ankylosis with wasting of the triceps and biceps, and tuberculosis with secondarily infected sinuses.

General anesthesia has been the rule but brachial plexus block was used in one case. A pneumatic cuff tourniquet is applied to the upper arm. The arm is held by an assistant across the patient's chest, the posterior aspect thus being uppermost. The surgeon stands on the side of the patient opposite the affected elbow. A 5 inch midline posterior incision is made centered over the tip of the olecranon, and carried down to the deep fascia. Skin towels are then applied. A nontouch technique is used throughout. An excellent detailed description of the operation is given.

The drain is removed after 2 days, and the stitches after 14 days. After 4 days the arm is flexed to 45 degrees on the adjustable splint. After a further 3 or 4 days it is extended to 45 degrees beyond the right angle, and then alternately flexed and extended at similar intervals until 3 weeks have elapsed when the splint is exchanged for an arm sling. The chief purpose of the splint during these 3 weeks is to control lateral movement of the elbow. In about 30 per cent of these cases there was a weakness of the muscles of the forearm, especially of the extensors of the wrist and fingers, which disappeared after from 10 to 14 days. In these cases a plaster cock-up splint was applied for 2 weeks.

At the end of 3 weeks the patient is ready for rehabilitation. The arm sling is worn for 2 weeks to prevent lateral movement of the false joint. In fractures and early tuberculosis it is discarded at the end of this time. In advanced tuberculosis and when there is gross wasting of the biceps and triceps it may be required for a period of several weeks or even 2 or 3 months.

After the first month of physical therapy the patients who had fractures are instructed to saw wood each day. The tuberculous patients are given this exercise after 2 or 3 months. In the fracture cases the patients can flex and extend the elbow against resistance and control lateral movement of the joint after 3 or 4 months they are then discharged. The fact that the patients can use the affected limb for sawing logs gives a fair estimate of its future usefulness.

In one instance a gross fibrosis of the biceps and triceps developed 5 months following the resection of the elbow. An arthrodesis of the elbow was then performed. Prior to the latter operation there was passive motion over the full range of motion. This was the least successful result in the entire series.

C. FRED GORDON, M.D.

Epiphyseolysis of the Hip. Discussion and Results (Epifisiolisi dell'anca. Considerazioni e risultati). A. ZARATTINI. *Chir. org. mod.* 947 31. 269.

The term "epiphyseolysis" is applied to the first stage of the condition which leads to coxa vara or valgus, according to the predominating static and dynamic factors. In the majority of cases in children coxa vara results.

The author draws the following conclusions from his observations on 10 cases.

The onset of this condition is slow and offers great diagnostic difficulties in the beginning.

The relations between trauma and epiphyseolysis are obscure. Apparently endocrine disorders play an important role in the pathogenesis of the condition but the exact mechanism of the effect is still unknown. The intimate genesis of the osteochondrogenous dysplasia requires further investigation.

The author rejects open reconstruction of the femoral neck, using metal for osteosynthesis although some writers advocate the method even in early stages of the disease. The surgical trauma causes a grave disturbance of the local trophic conditions and therefore the operation should be reserved only for exceptional cases. Whenever possible, arthrotomy should be avoided and subtrochanteric osteotomy done.

Bloodless reduction according to the Lorenz-Whitman method, combined with multiple perforations of the femoral neck, usually furnishes excellent results.

JOSEPH K. NARAT, M.D.

FRACTURES AND DISLOCATIONS

Internal Contact Splint. G. W. N. EGGERS. *J. Bone Surg.* 94B, 30-1. 40.

On the basis of bone atrophy at the site of fracture and the presence of inactive devitalized interfractural tissue delayed or even nonunion may follow when rigid commercial bone plates are used. During a deep anesthesia, the fascial as well as the muscle components are relaxed. At the cessation of narcosis the muscular tone returns and the combined longitudinal forces induce a sustained contact during the healing phase. If a gap has been created by distraction or absorption of the fractured ends, nonunion or delayed union is inevitable. Assuming that nonunion may ensue solely from rigid bone plates, the author has introduced a new plate which permits gliding of bone if and when shortening of the bony fragments occurs. Attention is drawn to the high frequency of nonunion of the tibia when the fibula remains intact. Similarly fracture of one bone of the forearm without the other is not infrequently associated with delayed union or nonunion. The involved mechanism is alleged to be an absorption or attrition of the fractured ends without compromise and resulting in an anatomical defect. Nonunion occurs.

Advantages of the internal contact splint are:
1. The fragment ends are easily placed together in exact approximation; the muscle pull will maintain the desired contact.

2. Oblique fixation screws across the fractured ends are eliminated. Hence the fragment ends do not receive additional surgical trauma.

3. Impaction of the fragment ends is undesirable nphysiological and unnecessary. It provokes attrition.

4. Absorption of the bone fragment ends is automatically compensated for by longitudinal muscle tone.

5. Fewer screws are necessary. Hence there is less bone trauma.

6. The internal bone splint is flat and pressure on the bone and periosteum is minimal.

7. There is less stress on the splint to break or bend at the fracture site. Dead space is eliminated by the telescoping mechanism permitted by the author's bone plate.

The article is replete with many roentgenological studies of long bone treated by this technique. Additional photographs show the method of testing beyond reasonable doubt, the longitudinal gliding of the screws and splint.

SAMUEL L. GOVERNALL, M.D.

Operative Therapy for Slipped Upper Femoral Epiphysis. An End Result Study. CARL E. BADOLEY, A. S. ISAACSON, J. C. WOLGAST and J. W. MILLER. *J. Bone Surg.* 1948, 30-A 19

In the treatment of displaced femoral epiphysis the authors have governed their therapy of 78 hips by the following principles.

1. A displacement of not more than one third of the diameter of the femoral epiphysis is treated by internal fixation without correction of the "preslipping" femoral head.

2. Greater displacement than in the preceding paragraph and associated with deformity and disability is dealt with by corrective operative procedures.

3. Skeletal traction for the traumatic and early slipping produces the most satisfactory results. For the maintenance of reduction mild manipulation and internal fixation is advocated.

4. For unsuccessful skeletal traction open reduction with a wedged osteotomy and a pin or screw fixation of the slipped epiphysis is practiced (in this group).

5. The ultimate result in cases of neglected and displaced femoral epiphysis is degenerative arthritis. Subtrochanteric or intertrochanteric osteotomy is reserved for this class of hip deformity. The authors treated 34 of the 78 hips by open reduction, removal of an anterior cuneiform wedge of bone and fixation by means of a Smith Petersen nail or by two screws. Eleven patients were subjected to an osteotomy at the epiphyseal site for the correction of deformity. Reduction was maintained by means of external fixation with a plaster spica. Four patients were subjected to osteotomy for alignment of the existing epiphyseal neck derangement. Six patients were treated by closed reduction, mild manipulation and blind nailing. Sixteen hips were fixed

internally with no attempt to correct minor displacements and 4 hips were corrected by the Schanz osteotomy.

The exposure of the hip is accomplished by the anterior Smith Petersen cup arthroplasty approach. The iliopsoas muscle is exposed cut and retracted medially. An excellent exposure of the anterior acetabulum is thus obtained. If possible the labrum glenoidale should be preserved. In order to aid in the location of the osteotomy level the anterior periosteum should be reflected care being taken however not to strip or injure the posterior perosteal elements as irreparable circulatory damage may ensue. Since in former years external fixation of similarly treated cases with a plaster of Paris spica resulted in 50 per cent of failures internal fixation with the Smith Petersen nail or screw is now done routinely. In the postoperative care adequate wound healing should be considered. Early ambulation is recommended and weight bearing should be possible 3 months after operation.

The aggregate clinical results attained by the combined operative procedures mentioned were excellent in 43 patients (57%) good in 8 (11%) fair in 1 patient and poor in 23 patients or 31 per cent. The end results in 38 patients treated by open reduction with internal fixation were graded as excellent in 21 (55%) good in 4 (11%) fair in 1 patient and poor in 12 patients.

The complications encountered by the writers were those of degenerative arthritis in 18 patients (23%) aseptic necrosis in 3 (4%) nonunion of the epiphysis in 1 patient (1%) and crushing of the neck in another. The latter complication resulted from an overzealous forceful manipulation of the deformity a preventable complication indeed.

In conclusion the authors assert that open operative correction by transcervical osteotomy and internal fixation yields the best chances for a good functional hip. When a slipped femoral epiphysis with malunion existed normal restoration of the femoral head and neck relationship by surgical means resulted in permanent good hip function in 68 per cent of the cases operated upon by the authors method.

SAMUEL L. GOVERNALL, M.D.

Disturbance of Longitudinal Growth Associated with Prolonged Disability of the Lower Extremity. DONALD ROSS. *J. Bone Surg.* 1948 30-A 103.

This article is concerned with premature closure of the growth cartilages at the knee in patients who have had prolonged dysfunction of the lower limb. It is based on the study of 13 patients of whom 9 had tuberculosis of the hip. Each of the others had pyogenic arthritis of the hip. A slipped capital femoral epiphysis, poliomyelitis or osteomyelitis of the shaft of the femur. Inequality of limb length resulting from growth retardation and not entailing premature closure of epiphyseal cartilage is not discussed herein.

In the cases here recorded the site of the growth arrest at the knee varies. In 5 patients, growth arrest

occurred in both the distal femoral and proximal tibial epiphyseal plates. Premature closure of the distal femoral disc occurred centrally in all 5 but in the tibial disc it occurred peripherally in 4, and centrally in 3. In 8 patients growth arrest of only the proximal tibial epiphyseal cartilage developed. Peripheral fusion occurred 6 times and central fusion twice. Seven of the peripheral arrests occurred in the posterior medial quadrant and 3 in the anterior quadrant of the tibial plate. The proximal fibular disc was not affected in any case which led to relative lengthening of the fibula proximally.

The 13 case histories are presented and representative roentgenograms are reproduced. Inequalities of leg length up to 17 cm are recorded. Photomicrographs of a prematurely uniting tibial epiphysis and its normal corresponding proximal fibular epiphyseal plate are reproduced.

Roentgenographic evidence of growth disturbance at the knee is usually present prior to the development of marked inequality of limb length or alignment deformity. The early changes are not observed unless repeated roentgenographic examinations are made from the onset of the disability to the end of the active growth period. Seven cases in this group were followed up for this length of time.

The early alterations of the epiphyseal cartilage are thinness of the epiphyseal disc and the presence of a transverse zone of dense bone on its metaphyseal aspect. Growth retardation scars are numerous and osteoporosis of the regional bone is pronounced. The contour of the epiphyseal cartilage is irregular with one or more peaks projecting into the metaphysis. Such changes may precede actual cessation of growth but in some cases, recovery of normal longitudinal growth occurs.

In the distal end of the femur the point of arrest is commonly posterior to the central portion of the disc. The remaining disc may continue to grow causing posterior rotation of the condyles. In the proximal end of the tibia the arrest is often in the posterior medial quadrant, in which case continued growth of the remaining cartilage results in tibia vara. When the tibial tubercle unites prematurely tibia recurvata occurs.

The essential pathological change is degeneration of the epiphyseal cartilage and its replacement by bone.

Prevention of growth deformity in chronic diseases of the lower extremity is not always possible. Measures to shorten the duration of disability from hip disease (such as operative fusion), avoidance of prolonged immobilization and careful supervision of the patient who resumes weight bearing on a limb which has undergone marked osteoporosis may minimize the chance of growth arrest. Epiphyseal arrest operations, osteotomies or leg shortening or lengthening procedures may be necessary for the best results in these cases. If asymmetrical growth arrest has occurred, alignment deformity must be prevented by producing a complete arrest of growth in that epiphysis by surgery.

Although the growth-retardation changes discussed are more pronounced at the more rapidly growing epiphyseal plate at the distal end of the femur actual premature closure was observed more frequently in the proximal end of the tibia.

Gill had suggested that this bridge across the epiphysis forms as a result of a rupture of the epiphyseal disc when the normal support of the disc collapses with fracture of the adjacent atrophied trabeculae. An alternate explanation of the growth arrest in these cases is that the already partially degenerated cartilage is unable to withstand the abnormal stresses of a faulty gait. The cartilage wears through at the point of greatest stress and allows bony union of the epiphysis and metaphysis. In favor of this is the high incidence of growth arrest in the posterior medial quadrant of the proximal tibial plate, and the fact that growth arrest never occurred in the fibula, which is unimportant in weight bearing.

KIMMEL H. SPORRELL, M.D.

ORTHOPEDICS IN GENERAL

An Anatomical Study of the Mechanics, Pathology and Healing of Fracture of the Femoral Neck. A Preliminary Report. ALAN D. FARNS, M.D., J. WILSON and J. CLIFFORD HAYTER, J Bone Surg 94B 30-A 33.

This article is based upon gross microscopic and roentgenologic anatomical studies of numerous femurs both fractured and unfractured. Special emphasis is placed upon the lamellar bone system within the neck of the femur. The authors undertook this study because they believed that the answer to the problem of injuries and healing of the femoral neck was dependent upon the condition of the internal weight bearing system of the lamellar bone within the neck of the femur. They noted that abduction fractures are caused by falls or compression of the trochanteric region, whereas adduction fractures are often or usually produced by trivial trauma.

The authors have demonstrated an uninterrupted lamellar system, which they term "the internal weight bearing system of the femur" running from below the lesser trochanter to the region of the cartilaginous plate of the femoral head. This system becomes merged with the cortex at the posterior femoral neck and from that point proximally it tends to fan out into a diffuse weight bearing system which ends at the cartilaginous plate of the femoral head. There is a reciprocal relationship between the strength of this structure and the cortical shell. The system is weakest where it fuses with the posterior cortex of the neck, and at this point the cortex is strongest. The system is strong where it enters the head in fanlike fashion and at this point the cortex is thinnest. The internal weight bearing system starts to undergo slow resorption after middle age, but it never disappears entirely. In advanced age the system is composed of laminae throughout its course. The proximal end becomes sparse. The reddish color of the distal portion of the internal

weight bearing system seen in younger individuals becomes whitish in the aged

This bone system is significant for three reasons

- 1 It is intimately connected with weight bearing
- 2 It is the chief source of bone repair
- 3 Its partial resorption in old age is the main pathological factor preceding fracture of the neck of the femur

This system has been written up by previous investigators under various names such as *calcar femorale* and *lamina femoralis interna*. The proximal portion of this system has been shown to be missing in primates and quadrupeds. In pathological conditions in which the line of weight bearing changes, this lamellar system changes accordingly. The authors believe this system is a pure compression system, having nothing to do with tensile stresses which they do not believe are important in the physiology of the hip

This internal weight bearing system consists of laminae sandwiched between layers of bone marrow and is ideal for speedy repair after injury if it is strong and healthy and in close apposition. If the structure is pathological healing will probably not take place.

In abduction fractures the internal weight bearing system breaks at about the middle of the neck but the cortex breaks at the cervicocapital juncture. Often in this type of fracture the internal weight bearing system is not completely broken but is "greenstick" in type, and heals rapidly even without treatment. Often there is impaction of such fractures.

The roentgenographic signs in fracture of a hip with a normal internal weight bearing system show (1) that the laminae are numerous and densely packed and (2) that the proximal fragment of the

internal weight bearing system is long and blunt, but not pointed

Adduction fractures occur in the subcapital region and the separation line of the cortical fracture and those of the internal weight bearing system are in the same plane. When the marrow deteriorates the proximal end of the internal weight bearing system loses its blood supply and separates pathologically. The distal ends of the system are intimately related to the cortex and draw their nutrition from the capsule and periosteum.

There are two distinct types of fractures of the neck of the femur

- 1 Compression fractures in which the internal weight bearing system is healthy
- 2 Subcapital separations with subsequent fracture of the cortical shell (These are always adduction fractures)

The first type according to these authors may heal in from 4 to 8 weeks with good apposition and fixation. The second type requires either replacement of the internal weight bearing system by bone grafting or its stimulation by biological mechanical or perhaps chemical means. Nailing or drilling seems to stimulate new bone formation. Accurate contact between the conical end of the proximal fragment and the distal portions of the lamellar system, or the graft which replaces this system is essential. The authors use a perforated graft from the femoral shaft just distal to the trochanter. The spongy side of this is faced posteriorly and has been successful in promoting union.

This article is accompanied by numerous photographs of anatomical specimens, which the authors prepared. Illustrative roentgenographs and photomicrographs also are furnished in support of the authors' conclusions. NEWTON C. MEAD M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Ligation and Division of the Abdominal Aorta for Metallic Embolism from the Heart. FAR RICE W. COOPER JR., M. D. ILL. 114 516, and J. W. KANE. *A. Surg.* 945 171

The authors review briefly the history of ligation of the abdominal aorta (an aneurysm first reported by Sir Astley Cooper in 1817. Thirty six cases of partial or complete ligation of the abdominal aorta appear in the literature and 12 of these successful results are obtained).

The case reported by the authors is the only one in which excision of the bifurcation of the aorta was necessitated by erosion of a portion of the wall of the aorta by a foreign body within its lumen. An uneventful clinical recovery occurred. The patient was a 22 year old male soldier who sustained a penetrating wound of the left arm and chest beneath the left breast with a .45 caliber pistol. Roentgenogram showed the foreign body in the heart. Later it was shown to have been carried to the bifurcation of the aorta. A detailed discussion of the clinical progress of the patient together with the operative procedure is presented.

The authors note that the embolism present in this case gave a typical sequence leading to ligation of the aorta. The patient was young with normal elasticity of youth. Occlusion of the aorta was not sudden but progressive. It was complete in one week with various signs of the completeness of obstruction to blood flow. Finally at the time of operation the vessel had become completely occluded and a large collateral circulation had been established. Operation in this instance actually immediately improved the circulation in the legs as shown by the prompt rise in skin surface temperatures of the toes.

Occlusion of the vessel was accomplished with No. 00 braided silk ligatures followed by complete division of the aorta. It is believed that with ligation and division of the large vessel ligatures of malleable may be used with safety.

HERBERT F. THURSTON, M.D.

Control of Arterial Hemorrhage by a Gelatin Sponge "Cuff" and Chronic Surgical Gut Sheaths. A New Experimental Method. HILTON PERRY, JERKINS EDWARDS, Sr., L. HOWARD OWEN, and ROBERT JACOBSON. *Arch. Surg.* 947 55 637

Reports on the management of vascular injuries in the recent war indicate that in only a relatively small proportion of the acute arterial injuries has it been feasible to resort to suture anastomosis or vein graft with the aid of vitallium tubes. The results in these cases from the standpoint of the prevention of gangrene have not been especially satisfactory as compared with the cases in which ligation was done.

In view of the satisfactory results which were obtained in the control of hemorrhage from wounds of

the vena cava and other veins in dogs by the gelatin sponge patch it appeared plausible to attempt control of arterial hemorrhage with this new hemostatic agent. A technique was devised which consisted of wrapping a "cuff" of dry compressed gelatin sponge about the wound in the artery and surrounding this with a sheath of chronic surgical gut. With this method it was possible to control hemorrhage and restore blood flow in wounds of the aorta (in experimental animals) without having to resort to arterial suture.

A cuff was made of dry gelatin sponge which had been compressed with the fingers until it was pliable and could be rolled into the form of a tube. When such a cuff was used alone it held only by sutures, the gelatin sponge was rather easily fragmented and blood clots occurred. In 16 animals in which the gelatin sponge cuff was supported by a sheath of chronic surgical gut there was only one blowout from the arterial wound. In one instance however a large propagating thrombus was adherent to the wound in the vessel wall. Induration of the tissues was observed about the sheath in several instances.

Microscopic studies revealed healing of the wound in the wall of the vessel by scar formation which was covered by a newly formed intima. The chronic surgical gut sheath was found to be present in varying stages of absorption. The gelatin sponge was generally found to be in more advanced stage of absorption than the surgical gut sheath.

The authors suggest that this experimental cuff technique might have some clinical application in circumstances in which a satisfactory arterial repair is not feasible by the standard suture technique. It is probable that its most potential field of usefulness would be as an additional guard against blowout of an arterial suture line. THURGOOD, D. BLASZCZYK, M.D.

Restoration of Endoneurysmothaphy by Vein Graft Inlay. ARTHUR H. BLAKEMORE. *A. M. Surg.* 1917 16 831

For the cure of aneurysm of the extremities the salient feature of the technique advocated by Blaszyk is the preservation of collateral vessels through an intravascular approach. It is the wish of the author to present herewith a technique of vein graft inlay for the repair of degenerative arterial aneurysm with restoration of the blood flow which conserves the principle of minimal damage to the collateral vessel. The technique of the procedure is described.

While one operator is exposing the aneurysm and securing free access to the proximal and distal poles, the assistant surgeon proceeds with the removal of a segment of vein for use as a graft—preferably from another extremity. The superficial femoral vein is most commonly used. When the afferent artery is located and isolated by blunt dissection a double turn of vaselized umbilical tape serves well

for temporary occlusion of the artery. The efferent parent artery is likewise identified and controlled. The aneurysm sac is then opened widely from pole to pole. The clot is evacuated and a search is made for openings of vessels within the sac. All vessel openings exclusive of the parent artery openings are sutured with three zero Deknatel silk from within the sac. The distance between the parent artery openings within the sac is measured. To this measurement 4 cm. are added for the correct length of the vein graft to be used to bridge the arterial defect.

Vitalium tubes, as recommended in a nonsuture method for vein graft bridging of arterial defects serve as a prosthesis for retention of the vein graft inlay. On account of vein valves the proximal end of the vein graft should be joined with the distal artery opening. A series of drawings are presented to illustrate the different stages in this technique.

Four cases are presented in detail and it is of interest to note that analysis of the 4 cases operated upon by the vein graft inlay technique revealed the restoration of a pulsating arterial blood flow with the salvage of all important collateral vessels.

The author concludes that in the light of the facts presented it is to the best interest of the patient to restore a pulsating arterial blood flow if it can be accomplished without damage to the important collateral vessels. Endoaneurysmorrhaphy with a vein graft inlay restores a pulsating arterial blood flow without damage to important collateral vessels.

HERBERT F. THURSTON, M.D.

BLOOD TRANSFUSION

A New Technique for Replacement Transfusion in the Treatment of Hemolytic Disease of the Newborn Infant. DOUGLAS P. ARNOLD and KENNETH M. ALFORD. *J. Pediat.*, St. Louis, 1948, 32: 113.

Replacement transfusion rids the blood stream of the infant with hemolytic disease of the newborn to

a considerable extent of Rh antibodies products of hemolysis, and of red cells of the infant which are sensitized to otherwise compatible serum of the adult.

Ordinary transfusions do not accomplish this. A replacement transfusion should be done as soon after birth as is possible. Early thrombosis makes umbilical vein transfusion impossible after the first 12 hours of life.

There is no superficial vein in the infant large enough to obtain blood rapidly and in sufficient quantity. The authors describe a technique whereby the greater saphenous vein is used high in the thigh. An incision is made medially and parallel to the inguinal ligament from 1 to 1.5 cm. below a point bisecting a line joining the anterior superior iliac spine and the pubic tubercle. The vein is exposed and ligated distally. One of Diamond's plastic catheters is inserted through the exposed saphenous vein into the femoral vein or inferior vena cava. When an adequate pool of blood is encountered 500 c.c. of blood are exchanged 20 at a time. This effects an 80 to 85 per cent transfer. Clotting within the apparatus is prevented by means of 150 c.c. of saline solution containing 10 mgm. of heparin per cubic centimeter but this is not allowed to enter the infant's circulation. Transfusion should take from 1.5 to 2 hours. In severe anemia from 20 to 40 c.c. more blood can be injected than is withdrawn. The blood which is transfused should be slightly warmed.

Following transfusion 10 c.c. of 5 per cent calcium gluconate are given to counteract the citrate used. The baby is kept warm and given oxygen during and after the procedure. Sulfadiazine (1 gr. per pound per day) and penicillin (3,000 units every 3 hours—intramuscularly) are then given prophylactically for 3 days. Also 1 mgm. of vitamin K is given by hypodermic injection every 6 hours for 4 doses.

JAMES WEAVER, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE; POSTOPERATIVE TREATMENT

The Value of Preoperative Heart Examination.
WOLFRAM KOCK *Acta Chir Scand* 1947 96 199

In determining whether a surgical problem is one of operation or of expectance it is sometimes a purely internomedical factor which decides the question namely the status of the patient's heart. It seems reasonably obvious that careful study of the anamnesis, of clinical and cardiac functional tests and of a consideration of the planned intervention together with the contemplated anesthetic and after course is of great importance in estimating what the patient can stand but to judge from reports in the literature a decision in this delicate question is not very easily made.

After citing some of the important studies of recent years dealing with the value of preoperative heart examinations it is given the results obtained in a series of 406 routine consecutive general surgical cases in which a detailed preoperative estimate of the cardiac status was made.

These cases involved the following organs and systems: the thyroid gland (100) the thorax, pleura, lungs, bronchi (44) the gall ducts, pancreas, spleen (53) the stomach and duodenum (49) the intestines, rectum and anus (39) and the kidneys and genitourinary tract (100).

Numerous tables are included which show the condition of the patients with respect to age, sex, previous cardiac history, physical and laboratory findings of cardiac aberration, electrocardiographic changes, and heart pathology as shown in roentgenograms, and each table lists the incidence of postoperative heart complications. The frequency of pathologic electrocardiographic and roentgenographic findings in patients who, from the history and physical examination were adduced to have a normal cardiac status is emphasized.

Insofar as anesthesia was related to postoperative complications, lumbar puncture was most frequently involved, but here analysis is difficult in that 3 complications occurred following the use of local anesthesia.

Postoperative heart complication occurred in only one case in which the preoperative estimate had been of a normal cardiac status and in this case the issue was not fatal.

In the total series 12 deaths occurred and these were attributed to cardiovascular causes; each case is described in detail. The author concludes that an adequate preoperative estimate of the cardiovascular condition of a patient is possible only when the complete anamnesis, physical findings and laboratory examination, as well as the electrocardiogram and roentgenogram of the heart are all considered.

WAYNE F. CAMERON, M.D.

Discussion on Postoperative Thrombosis. HENRY PAVLING, WRIGHT, MARGUERITE HAINES, A. DICKSON, WRIGHT, LESLIE WILLIAMS, and Others. *Proc. R. Soc. M. Lond.*, 1948, 41 17

WRIGHT concluded from studies on 4 patients following operation and delivery that increases in the fibrinogen W fraction and the prothrombin activity could not be used with any degree of accuracy to predict the onset of thrombosis. In 1942 she found that the platelets increased and became more adhesive following trauma incident to operation or delivery. This was most pronounced on about the tenth day. It was concluded that the increase in the stickiness resulted from the presence of the new young cell. The degree of elevation of the platelets was found to be dependent upon the amount of tissue damage and autolysis. By casting the iliofemoral segment of veins with plaster of Paris a marked anteroposterior flattening was observed where the vein passes over the pelvic brim. This was attributed to the vein lying almost directly on the bone and next to constriction by the inguinal ligament. The slowing of blood flow and nipping of the clot at the point were considered as possible factors in the formation of repeated emboli. In the Fowler position the vessels were found bent almost to a right angle. Currently studies are being carried out with radioactive isotopes on the rate of venous flow of the leg in an effort to further elucidate on the problems of stagnation in patients confined to bed.

HAINES reviewed the operations performed at the Chelsea Hospital for Women from 1927 to 1946 in order to ascertain the trend of fatal pulmonary embolism. Statistical analysis indicates that the chances were 40 to 1 that the death rate would fall in the second to year period as compared with the first and the best estimate of this fall was from 4.73 per 1,000 operations to 2.22 per 1,000.

WRIGHT favored interrupting the superficial femoral veins and using anticoagulant therapy preoperatively for individuals predisposed to thrombosis. This was also recommended if pulmonary embolism occurred. The common femoral vein is interrupted above the saphenous opening in the presence of thrombosis of varicose veins or normal superficial veins. Posterior tibial phlebotomy is treated by superficial femoral vein ligation at the junction with the deep vein on the affected side along with the usual anticoagulant therapy. Iliopsoas, iliofemoral, iliac, femoral, and popliteal thrombosis is treated by ligation of the superficial femoral vein at the junction with the deep vein on the affected side along with the usual anticoagulant therapy. Iliopsoas, iliofemoral, iliac, femoral, and popliteal thrombosis is treated by ligation of the superficial femoral vein at the junction with the deep vein on the affected side along with the usual anticoagulant therapy. Iliopsoas, iliofemoral, iliac, femoral, and popliteal thrombosis is treated by ligation of the superficial femoral vein at the junction with the deep vein on the affected side along with the usual anticoagulant therapy.

WILLIAMS advocated anticoagulant therapy and paravertebral sympathetic block for any patient in whom venous thrombosis in the deep veins of the

leg is diagnosed. He did not, however, urge early amputation or femoral vein interruption to save nothing of caval ligation.

BALL reviewed 46 cases of venous thrombosis and pulmonary embolism treated with anticoagulant drugs at Central Middlesex County Hospital. He found this regimen shortened the hospital stay to about 3 weeks and the stay in bed to about 1 week. Moreover, the risk of pulmonary embolism appeared to be lessened and it seemed likely that the percentage of disabling after-effects would be markedly diminished.

GREEN ARMYTAGE pointed out that notwithstanding the attending trauma, embolism and thrombosis rarely follow pelvic operations from below.

DWIGHT H. LYNN, M.D.

Anticoagulant Treatment of Postoperative Venous Thrombosis and Pulmonary Embolism. JAMES A. EVANS and JOHN F. DEZ, *England*, *J. M.* 1948, 238, 1.

Among 56,000 patients who underwent major surgical operations at the Lahey Clinic, Boston, the incidence of thromboembolic disease was 0.42 per cent (184 cases). In 33 per cent of the cases there was a warning pulmonary embolism. Not included in the 184 cases were 54 patients who died before the diagnosis had been made or treatment had been instituted. Among the group of patients who had had treatment, there were 6 fatalities. Of these 3 may be partially regarded as therapeutic failures. Hemorrhage following dicumarol therapy developed in 12 patients, with death of one patient. Since the use of anticoagulant therapy, the mortality has been reduced to one fourth that for the year of 1945 and to one-half that for the year of 1946 in the same institution.

Anticoagulant therapy for venous thrombosis and pulmonary embolism has superseded other methods of therapy at the Lahey Clinic. In only 10 of the 184 cases was venous ligation carried out as a complementary measure. The indications for venous ligation have been limited to the following conditions: hemorrhage, severe liver disease, ambulatory phlebothrombosis with pulmonary embolism, resistance to anticoagulant therapy of both heparin and dicumarol, recurrence of embolism after adequate therapy, and to prophylactic ligation in patients over 60 years of age. Prophylaxis against venous thrombosis consisted of early ambulation and the infiltration of dicumarol on the fourth postoperative day.

The following institutional orders are applied in all patients confined in bed. Patients are instructed to exercise the toes and feet one thousand times daily; elastic bandages are applied to the limbs of all patients with varicose veins during their entire stay in bed; daily inspection is made to discover an unexplained fever, pain in the calf, or the presence of a positive Homan sign; warning signs are plainly stamped on all charts containing the histories of previous venous disease. In patients receiving dicumarol therapy, determinations of the prothrombin time are made daily

in the morning before renewal of the drug in patients receiving both dicumarol and heparin; the coagulation time of the blood is also ascertained; excessive bleeding due to dicumarol is controlled by the intravenous administration of vitamin K—that due to heparin by transfusion of fresh whole blood. Refractoriness was recognized by failure of the prothrombin level to fall below 0.5 per cent of normal during the administration of adequate doses of dicumarol. Heparin in Pitkin's menstruum was given to 55 patients and proved to be a safe and practical method of treatment.

BENJAMIN G. P. SHARROFF, M.D.

Pulmonary Embolism. RICHARD R. CRUTCHER and R. LEE A. DANIEL, JR., *St. Mary* 1948, 23, 47.

The clinical and autopsy records of patients treated at the Vanderbilt University Hospital, Nashville, Tennessee, over a period of 15 years were analyzed from the standpoint of pulmonary embolism. In that time there were 84,004 admissions, 35,540 operation, 4,182 deaths and 1,550 autopsies. Pulmonary embolism was the causative factor of death in 55 patients, 25 of these had been treated surgically and 30 had had medical treatment. One third of the deaths occurred in individuals under 40 years of age. In the patients who were operated upon emboli occurred within 10 days. The emboli were located in the veins of the lower extremities in 51 per cent of the patients. Patients who succumbed to pulmonary embolism were classified into three groups: (1) those not regarded as seriously ill; (2) those seriously ill with an indeterminable outcome; and (3) those for whom a fatal outcome was expected regardless of pulmonary embolism. The greatest proportion of deaths occurred in the first group and the smallest in the third group.

In some cases clinical signs of phlebitis were masked by edema of the lower extremities and were accounted for on the basis of cardiovascular disease or malnutrition. Autopsy venous thrombi were located either in the extremities or in the lungs. Although 10 patients had shown evidence of attacks of pulmonary infarction, clinical signs of phlebitis were demonstrable in 3. Pulmonary infarcts were found at autopsy in 26 of the 55 patients and of the 16 died of a single embolus. All of the patients operated upon died of massive embolism involving the large pulmonary arteries. In 40 per cent of the patient thrombi involving pelvic and abdominal veins were located cephalad of the superficial vein.

BENJAMIN G. P. SHARROFF, M.D.

ANTISEPTIC SURGERY, TREATMENT OF WOUNDS AND INFECTIONS

A Study of Burns and Scalds in Children. BENJAMIN MORRISON, *Arch. Dis. Child.* 1947, 22, 122.

Between June, 1933 and March, 1946, 35 burns and scalds in children were studied. The lesions are classified according to Dupuytren's system and the author finds a significant relationship be-

tween the degree of the lesion and the constitutional disturbances. It is emphasized that the appearance of any burn or scald within a few hours of the injury is deceptively favorable. It is not until about the tenth day that the area of dead tissue is well defined and then it is often greatly in excess of what at first seemed likely.

During the first few days the clinical features of these injured children were carefully noted and reported. The observations of the blood pressure readings could not be considered reliable except in the quiet cooperative child. The blood examination provided data for estimating fluid lost from the circulation. The red cell counts were unreliable and soon discarded. The hemoglobin seemed reliable when done under uniform conditions but the prevalence of a hypochromic anemia among the children made it difficult to assess the values obtained. The hematocrit value tends to be more constant and gives a quick accurate result in a ward laboratory. Thus the hematocrit proved to be the most valuable single criterion of plasma loss and, in the later cases, was used exclusively for calculations. Values for normal blood and plasma volumes were used with the hematocrit readings for the estimation of plasma loss, as follows:

Case 30.—C. R. aged 3 years normal hematocrit for age, 35 per cent. normal blood volume for age, 750 c.c. normal plasma volume for age 490 c.c. abnormal hematocrit ($2\frac{1}{4}$ hrs. after scalding) 50 per cent. Let abnormal blood volume = x c.c. then (if total red cell volume, R , is constant)

$$\frac{35750}{100} = R = \frac{50x}{100} \quad \text{Therefore } x = \frac{35750}{50} = 715 \text{ c.c.}$$

The amount of plasma lost over $2\frac{1}{4}$ hours, 750—715 = 35 c.c. $\frac{35 \times 100}{490} = 7.1$ percent of total plasma volume

Despite all possible drawbacks of such a calculation as hemolysis or dilution, the treatment based on the formula was more satisfactory than when guided solely by clinical criteria.

The clinical picture may be divided into three successive phases: first fluid loss or concentration of blood second "toxemia" third secondary infection and wasting.

The phase of fluid loss and hemoconcentration was studied in detail. Steady fluid loss persisted for about 24 hours and a smaller loss for a further 12 to 24 hours, but the rate and duration of the loss seemed to vary considerably in different cases, other factors being equal. A composite picture of the usual and fairly constant physical signs and symptoms of progressive reduction in plasma volume and resulting hemoconcentration was obtained and divided into eight stages of fairly constant order of appearance. These are as follows: (1) rising pulse rate (2) thirst (3) coolness of the nose and extremities and mild restlessness (4) pallor coldness, and cyanosis of the extremities with narrowing pulse commencing drowsiness and vomiting (5) marked restlessness with mental confusion and falling blood pres-

sure (6) air hunger (7) loss of consciousness and (8) complete circulatory failure and death.

Death may occur within an hour of the onset of marked restlessness and mental confusion. In small children convulsions may appear at about stage 5 or 6.

The pulse rate appeared to be of little value in assessing the severity of the injury during the first 48 hours and the rate was affected by plasma reactions, temperature variations and restlessness, as well as by changes in blood concentration.

Cyanosis and pallor and coldness of the skin are indicative of peripheral vasoconstriction, and their appearance and persistence are important. In the author's series their absence did not necessarily mean that all was well but their appearance corresponded to a loss of 30 to 50 per cent of the total plasma volume.

The blood pressure readings were of some help in guiding treatment, but to wait for a marked fall in blood pressure before commencing intravenous therapy is to take unnecessary risks. Hypotension is always a significant, but usually a late, sign. Hypertension was most common and in the majority of cases it appeared only after the administration of plasma had begun.

The mental state followed a very characteristic pattern. During the first few hours after burning the children showed a striking composure they were alert, quiet, and appeared to have little or no pain. They usually had no complaints but asked repeatedly for drinks. As the picture advanced they often shivered and complained of the cold and asked incessantly for drinks. If they vomited they appeared unconcerned and asked immediately for another drink. At about this stage they tended to become drowsy they slept lightly and were readily disturbed. Restlessness then appeared and was characterized by sudden movements of the limbs shouting, and so forth. The spasms passed off as suddenly as they came on and the child was asleep in a few seconds. Drowsiness and mental confusion were noted at this time. Restlessness of this type was a manifestation of reduced plasma volume and striking relief followed efficient intravenous therapy. It is a danger signal and must never be disregarded. Sedatives, notably morphine given at this stage may mask the gravity of the situation. Sedatives are rarely necessary once the fluid loss has been relieved.

Comparison of the hematocrit levels with the clinical findings showed that the hematocrit was a more sensitive index of fluid loss and was considerably raised before clinical illness was obvious. There was a fairly close correlation between severity of the clinical illness and the amount of fluid loss. Stages 1, 2 and 3 corresponded with up to 30 per cent plasma loss. Stages 4 and 5 corresponded with up to 30 to 50 per cent plasma loss. Stage 6 corresponded in one case with 60 per cent plasma loss.

Before stage 4 is reached the signs are not obvious to the inexperienced eye and have always to be looked for. This would indicate that the clinical signs are

a rather late manifestation of a progressive state and that the only safe estimate of the seriousness of the fluid loss is obtained by direct blood examination. Three case histories illustrated these interesting observations.

The phase of toxemia is less well defined and established, and is made up of a group of signs which were related in time and frequency of occurrence. They were first seen toward the end of the first 24 hours and lasted for varying periods of time up to 8 weeks. They did not seem to be attributable to either fluid loss or to secondary infection and their rapid appearance and slow disappearance suggested the action of some toxin. The signs were not observed in all cases.

1 Sustained pyrexia and increased rate of depth of respiration were usually associated. The pyrexia differed from that of a secondary infection by the absence of irregular fluctuations and by its much earlier onset.

2 Hypertension during plasma administration was seen in 23 out of 27 cases in which readings were obtained. Its occurrence was directly associated with the depth of the burn but it was most marked where there was much sloughing.

3 Drowsiness and signs of increased intracranial pressure were present in 6 cases. All of these children had severe, deep burns and showed sustained pyrexia and hypertension.

The onset of cerebral signs with loss of consciousness occurred fairly suddenly between 19 and 33 hours but was preceded by drowsiness. Periods of apparent coma alternated with lucid intervals or restlessness.

Cerebral edema was usually considered to be the probable explanation of these phenomena. Lumbar punctures were not conclusive however and at the time of onset of the nervous symptoms all of the patients showed a hematocrit value above normal. The duration of the nervous signs was usually only 2 to 3 days. Seven cases illustrating the nervous phenomena are given.

The phase of secondary anemia and wasting was of importance only in lesions covering over 20 per cent of the body surface. In this series bacterial infection appeared about the end of the second or third week.

The wasting was rapidly progressive in the severe cases and tended to become stabilized after 4 or 5 weeks but showed no improvement until healing was well advanced. Some of the wasting can be attributed to aversion to solid food and a reduced caloric intake. Loss of appetite at any time was an omen. It was noted that appetite was often strikingly improved overnight by correction of the anemia with blood transfusion.

Anemia of a progressive character was seen in all severe cases even when obvious secondary infection was not present. The anemia was routinely corrected with blood transfusions. The most noticeable effect of anemia appeared to be a lowering of morale. These patients exhibit a profound emotional upset which

accompanies the physical illness and constant care is required to insure recovery.

Postmortem findings of 7 fatal cases are briefly reviewed.

Treatment of the local wound was delayed until relief and control of the fluid loss had been attained. The local therapy was that of careful cleansing with the gras or vaseline gauze and bandage with special care to bandage in such a manner as to completely seal off the lesion from the exterior. Dressings were repeated at 5 day intervals under general anesthesia. Skin grafting was commenced as soon as clean granulations appeared usually after 6 or 7 weeks.

The avoidance of a certain amount of secondary infection in some cases appears practically impossible. In the treatment of severe wasting the problem of feeding remains a difficult and all important one. To work out a satisfactory high protein diet, however and to persuade the child to take it were two quite separate problems. The interdependence of appetite morale anemia and secondary infection is very complex and of great importance.

As regards the treatment in the phase of fluid loss and concentration of the blood, it is essential that there be early recognition of the developing hemoconcentration. As more experience was obtained more reliance was placed on the hematocrit and the intravenous fluid was given with the aim of obtaining a definite value for this. In the majority of cases the actual and expected results for the amount of fluid given showed good correlation when based on the formula used. Saline solutions were found to be of little or no use in the relief of marked plasma loss but may need to be given in addition to plasma in cases in which the urine output is low and the child is unable to drink.

HARVEY S. ALLEN, M.D.

Hard Dorsal Post Traumatic Edema of the Hand
CLARENCE A. LUCKEY and HENRY D. MOON, *Plast Reconstr Surg* 1947 : 563.

Hard dorsal post traumatic edema of the hand has been observed for many years however pathological studies have rarely been carried out. Unless one is familiar with the affliction the true nature may not be suspected and proper treatment may not be carried out. The rarity of the condition undoubtedly accounts for the lack of clinical recognition in some instances.

As the name implies, the edema usually comes on following trauma and is localized to the dorsum of the hand. There is no pitting, the swelling is hard and it does not extend to the fingers or to the wrist. Early in the century individuals afflicted with this disability were suspected of malingering however since that time the organic basis has been recognized.

According to Iselin hard dorsal edema was first described by Secretan in 1901. Iselin states he personally has never seen a case. Tinel and Monod believe that a circulatory obstruction is present. They believe that there is vasoconstriction of the capillary and venous system and that transudation

occurs from the arterioles. Andre Thomas and Kudelski suggested that the edema may be due to an inflammatory process involving the lymphatics, venous system, and other tissues.

The authors are reporting on 2 cases of hard dorsal post traumatic edema of the hand incurred in the army and treated by excision of the mass.

The first patient, a white male was struck on the dorsum of the right hand by the recoil of a .75 mm. gun in March, 1914. A hematoma developed on the dorsum of the hand following the injury. This was removed a short time following injury. Hard dorsal swelling of the hand ensued and motion became quite limited in spite of extensive activity of the hand. In addition the patient had pain in the hand. X-ray therapy as given but no benefit noted. Since conservative therapy did not bring about any improvement in the condition excision of the mass was decided upon.

The cause of the hard dorsal post traumatic edema remains somewhat obscure. The macrophages containing hemosiderin suggest that the fibrous tissue formation may be secondary to hematoma formation in some cases. This is consistent with the clinical history in each of the authors' 2 cases. There is an unusual predilection to keloid formation. The mass removed is not unlike keloid material. This individual variation to scar formation may explain to a point at least why this process takes place in some injured hand and not in others. The microscopic sections show that the scar tissue is quite mature.

On the basis of this finding and also since reasonably good results follow surgical excision the authors believe that complete excision of the fibrous tissue mass is the treatment of choice. Skin grafting following excision of the mass may be of benefit. Since the fibrous tissue is mature spontaneous regression is not likely.

LEON T. BLAIR, M.D.

Pi. Split Repair of the Extremities by Nontubulized Pedicle Skin Flaps. JOHN MARQUET COVATTA, J. Bone Surg. 1918 30-A 63

The following observations are based on 781 operations for repair of surface defects of the extremities by nontubulized pedicle skin flaps. The pedicle flap because of its make-up of epidermis, dermis and subcutaneous fat, provides not only a skin dressing but adds elasticity and extensibility to joint surfaces, which allows for the normal stress and strain of everyday trauma.

Pedicle flap grafts are especially indicated in the following conditions: (1) to cover a surface defect over an area of active function such as the joints of the elbow or knee; (2) to provide a vascular integument over bone so as to allow for secondary operations such as bone graft or joint resection; inhibiting ischemic necrosis, osteomyelitis and sequestration; (3) for tendon repair to supply an inner adipose surface to keep tendons free from adhesions and provide sliding pathways for their action; (4) as a cover in the repair of peripheral nerves to minimize scar

formation with its concomitant effect on conductivity and pain.

Local or contiguous flaps are obtained from the vicinity of the primary defect, and are of two types: the transposed flap and the rotation flap, the latter comprising the swinging rotation and the advancement rotation types. Local flaps are applicable for the upper extremity and the ankle or foot, but are necessarily limited by the size of the defect and the character of the tissue. Distant flaps are called direct when they are immediately transferred to the recipient site and are indirect when migration is necessary before reaching the donor site. In cases in which viability is in doubt flaps are best delayed. Delayed flaps may usually be transferred after from 10 to 24 days. In the present series, 8 of 370 distant flaps were delayed. The mapping of a true defect of any extremity is best accomplished by outlining the defect on the unaffected limb and using fixed bony points for locating longitudinal and horizontal boundaries of the defect. A true defect should be distinguished from an apparent defect which is modified by scarring and contractures.

The following points should be observed in the planning of the flap: (1) the flap operation should cause little discomfort to favor complete immobilization; (2) the transfer should be as rapid as possible and (3) the flap should be derived from a suitable donor area. The design of the flap should be prepared in such a manner as to leave an optimum angle for its attachment and maintenance of its blood supply without kinking of blood vessels. The length of the flap should not be greater than one and a half times the width. Flap operations should be temporarily delayed during the period of redness and edema of wound margins, elevation of temperature, profuse discharge, or the identification of a hemolytic streptococcus present on wound culture.

For effective flap transfer, hemostasis and careful suture of the skin edges are necessary for primary union. The raw area of the donor site may be closed by a split thickness graft or sutured without tension when possible, by undermining of the tissue. The use of a hinge flap is a valuable method of eliminating the raw area under the main flap. Flaps are generally separated on the fourteenth day, but in the covering of denuded bone, 21 days are allowed before separation. Defects of the fingers, the interdigital spaces and the palm of the hand are repaired by cross arm flaps. Abdominal flaps are used to repair defects of the dorsum of the hand and forearm. The elbow region is best covered by a flap raised just above the iliac crest. Defects of the arm are covered by thoraco-brachial flaps. Cross leg flaps are used to cover denuded bones of the leg or foot, the position of the transfer depending on the location of the site of the defect. The inner half of the sole of the foot is covered by an oblique flap raised from the posteromedial aspect of the opposite leg. Failures in flap transfers are due to necrosis, infection, or improper postoperative care.

ANESTHESIA

Anesthesia with Intravenous Pentothal Sodium and Local Nerve Block in Gynecologic Surgery
JAMES C. MCCANN *N. England J. M., 1947 337*
931

Intravenous drop of pentothal sodium in a 1 per cent solution combined with local nerve block with 1 per cent procaine was given in 60 to 70 per cent of 2,000 general surgical procedures, and quantitative and pneumographic observations were made. In general it was found that the rate of administration of pentothal sodium was related to the need for the drug in the particular case as determined by the rate of metabolic destruction of the drug and duration of operation and its type depending on the neurologic segment in the peripheral area of distribution of the nerves in which the operation occurs. There was no evidence to indicate any so-called cumulative action of the drug for with reflex factors well controlled by procaine field block, there seems to be ample evidence of fixed level basic needs for the drug in each patient, even over an extended period. During the induction, pentothal was infused at the rate of 250 drops a minute until unconsciousness occurred. No further administration of the drug was made until the irregularities of respiration returned to normal then quantities of 10 c.c. every minute in patients under 50 years of age or 5 c.c. in thin small patients over 50 years of age were given. This was repeated from 2 to 4 times until surgical anesthesia was reached. Subsequent maintenance was obtained by the administration of pentothal at the rate of 130 drops per minute whenever recurring reflex stimulation of respiration by surgical trauma manifested itself.

In vaginal operative work a method of continuous administration of pentothal and ether was used in which, after the usual induction of pentothal in 1 per cent solution the drug was administered continuously in a 0.5 per cent solution at the rate of 30 drops a minute. Ether was administered continuously at the rate of 28 gm. an hour. Two gm. were considered the limit of pentothal after which ether alone was given to complete the operation.

The technique of transincisional procaine block of the intercostal nerves to the lower half of the rectus muscle is described. It was carried out after complete incision of the skin subcutaneous tissues and fascial anterior layer of the rectus sheath occurred. With this method 87 per cent of the male patients failed to exhibit adequate abdominal relaxation 72 per cent of the females who had a preceding pregnancy had adequate relaxation. Subsequent use of cyclopropane ether or curare with pentothal controlled the more powerful intra-abdominal reflexes. There was a reduction of 50 per cent in the need for pentothal as a result of peripheral blockage of all pain impulses by procaine field block, in a series of hysterectomies studied. There was an over all mortality for the entire group of .04 of 1 per cent and for major gynecological procedures .07 of 1 per cent.

Pneumographic tracings demonstrate the characteristic patterns of reflex response of respiration to trauma in the three neurological fields involved by surgical trauma during pelvic surgery.

Pentobarbital Sodium-Curare Induction for Endotracheal Intubation H. CARRON V. K. STOELET
DWO and S. C. CULLEN *Anesthesiology 1948 9 11*

Curare had been used in conjunction with nitrous oxide and with pentothal to provide anesthesia and relaxation for intubation with the tracheal tube. Results of these combinations were unsatisfactory in the authors' experience.

Reported observations of a synergistic hypnotic action of pentobarbital sodium and curare suggested the use of these agents prior to intubation.

The technique used was as follows:

Preliminary medication of morphine and scopolamine was administered. Intravenous fluids were started and a 5 to 6 per cent solution of pentobarbital sodium was administered through the infusion until the patient lost the lid reflex and did not respond to questioning. Dosage ranged from 98 to 293 mgm. with an average of 211 mgm. Oxygen was administered with a bag and mask and fractional doses of curare were given to provide relaxation of the jaw. The average dose of curare was 107 units, the dose varying from 50 to 200 units.

Intubation did not prove difficult when this procedure was followed.

A summary of cases in which this pentothal sodium-curare technique has been used is presented.

Advantages of this technique are rapid induction of anesthesia, a lack or minimal degree of laryngospasm, ease of intubation and rapid recovery from anesthesia.

MARY KARP M.D.

Glycogenolysis under Prolonged Use of Sodium Second and Sodium Phenobarbital in Dogs
NORMAN A. DAVID, NILEKANTH M. PHATAK, ROSA KUBIN and HERMAN F. VEHR. *Current Res. Anesth.* 1948 27 25

When barbiturates are used as preanesthetic agents the hyperglycemia caused by such anesthetics as ether which act principally on the cerebral cortex is reduced. In 6 dogs which were treated for a period of several months with daily minimal anesthetic doses of sodium second glucose tolerance tests performed during a 40 hour abstinence period showed a normal type of dextrose clearance curve. A second tolerance test performed on these dogs after a 10 or 21 day barbiturate withdrawal period, showed a definite trend toward increased tolerance. The livers of these animals at autopsy were normal on gross and microscopic examination.

The mechanism of this increased carbohydrate tolerance in dogs under prolonged barbiturate treatment is neither explained nor established. This effect may be due to some changes in the endocrine balance which are normally effective in the blood glucose regulating function of the liver or to a direct

metabolic protection of the detoxifying organ by preventing its glycogenolysis. These possibilities need further experimental exploration which is now in progress.

MARY FRANCES POE, M.D.

Endotracheal Anesthesia for Operations on Cleft Lip and Cleft Palate. M. D. LEITCH and H. A. KESTER. *Anesthesiology* 9:139-142

Some modifications of the usual endotracheal technique are used by the authors in anesthesia on children of less than a year old. Beyond that age the technique is not materially different from that in common use (Adrian child circle filter technique).

Premedication is somewhat unusual in that morphine and scopolamine are used in patients of any age. This has been the practice of the authors in more than half of their series of cases, over a period of 7 years. However, no dosage table is included.

Induction of anesthesia is accomplished with diethyl ether followed by diethyl ether both given by open drop. Very early use of an oral oropharyngeal airway is advocated to prevent obstruction by the tongue falling into the cleft in the palate.

Intubation is done in the second plane of stage 3 care being taken to flood the lungs with oxygen under the mask just before intubation. The patient's head is levated in a padded ring which enhances stability of the head and fixes the neck on the shoulders. The authors use their own modification of the laryngoscope with a wide blade narrowed antero-posteriorly and a bend upward of the blade at its tip. The width of the blade aids in preventing the end of the instrument from dropping into the cleft in the palate.

A soft rubber or vinyl plastic Magill tube lubricated with water soluble eupercaine jelly is used

Abduction of adducted cords may be obtained by blowing down a tube whose tip is placed at the pharynx. The pharynx is then sucked off. The authors offer comparisons and recommendations on the sizes and lengths of tubes used. Oral endotracheal tubes are long enough to reach from the lobe of the ear to the tip of the nose with 1 to 2 cm. in spare. No cuff is used on the tube as the cords soon accommodate to the tube and no anesthetic mixture is lost.

Maintenance is accomplished with an apparatus consisting of an endotracheal tube, a metal connector with a bore the same size as the tube, a short piece of rubber tubing, the metal piece containing the inhalation and exhalation valve (Leigh valve), a 2 liter reservoir bag, and a rubber tube leading to the gas feed. Nitrous oxide and oxygen are supplied if necessary either or cyclopropane is added for depth. The technique described was used in 34 per cent of the cases and Ayer's technique was used in 6 per cent.

Blood loss is replaced as it occurs, through a venous cut-down. Complications in induction are those of any open drop anesthetic. Endobronchial intubation is the most serious maintenance complication and accounted for one death. If rapid, deep respirations threaten to lead to collapse of the patient, double the premedication dose of morphine is given intravenously. Postoperative complications center about maintenance of the airway in an infant previously accustomed to more airway space than he now has.

Of the 493 patients whose cases are reported, 57 per cent were 5 years of age or under. Three deaths occurred: one from bronchial intubation, one from shock, and one from transfusion of incompatible blood.

MARY KARR, M.D.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

The Association of Achalasia of the Cardia with Esophageal Carcinoma P. BAER and K. SICHER
Brit. J. Radiol. 1947 20 528.

The association of carcinoma of the esophagus with cardiospasm or achalasia is not well recognized. The authors have found in the literature 8 such cases in which the clinical data were adequately included and 9 cases in which the clinical details were not available because of the wartime disposal of medical libraries. To these they added one case.

All of the tumors were located in the midesophagus (dilated portion) and nearly all were squamous cell carcinomas. The average age was 54.9 years and 80 per cent of the patients were males. The average lapse of time from the onset of achalasia until the carcinoma was identified was 19.3 years, and the symptom free interval after treatment of the achalasia was 7 years.

Because the tumor develops in the dilated esophagus marked obstructive symptoms do not appear even though the tumor may be quite large.

Roentgen diagnosis is difficult not only because the elongated tortuous esophagus may be filled with food but the demonstration of achalasia may be taken as an adequate explanation of the symptoms of the patient and the carcinoma may be overlooked. Loss of weight which is out of proportion to the duration of the symptoms of achalasia and the presence of blood tinged vomitus however are signs which are very suggestive of carcinoma.

The authors believe that achalasia produces conditions which are favorable to the development of carcinoma.

ROBERT BURNS LEWIS, M.D.

Special Roentgenographic Aspect that May Be Assumed by Primary Carcinoma of the First Part of the Duodenum (Sul particolare aspetto radiologico che possono assumere i canceri primitivi della prima porzione duodenale) DOMENICO BEZZETTI.
Arch. ital. med. exp. diger. 1947 13 353.

A short discussion of the difficulty in diagnosing malignancy of the duodenum is followed by the report of a case in which the diagnosis of carcinoma of the first part of the duodenum was made roentgenologically before operation and confirmed by surgical intervention. This is of great interest because (1) the precise location of the tumor was determined and (2) the neoplasm was diagnosed as a primary one in the first part of the duodenum.

The case could have been easily diagnosed as a primary tumor of a contiguous organ, a polyp of the stomach or duodenum, or as a gastroduodenal invagination but the increase in size and the rigidity of the duodenal bulb with its filiform channeling conveyed the idea that the tumor was primary in this part of the intestinal tract.

Cancer of the duodenum, because of the annular arrangement of the submucous lymphatics assumes a circular pattern. Viewed from within the lumen the neoplasm appears like a rigid valve ulcerated at times. When the tumor is located near the genu superior of the duodenum it will cause an enlargement of the bulbous portion which at times may approach a gigantic size. When the neoplasm is located near the pylorus the stomach is the part to become dilated the duodenal bulb appearing like a rigid canal.

The polypoid type has a tendency to ulcerate. There is however a malignant ulcerative type annular in shape which involves from one half to three fourths of the circumference of the viscus. It has a hard base the edges are raised and the growth bleeds easily. The serosal aspect of the bulb may appear normal or the bulb may be impregnated with cicatricial tissue when the ulcer is small. This type has been diagnosed as an ulcer by both the radiologist and the operating surgeon.

The roentgenographic findings are

1 In the annular type there is a more or less serrated stenosis. When the growth is juxta-pyloric there will be pyloric stenosis and when involving the genu superior of the duodenum the bulb will be markedly dilated and later will involve the pylorus and stomach. The diagnosis in these cases is difficult. A partial stenosis changes the duodenal bulb to an irregular small somewhat tortuous channel.

2 In the ulcerative type the diagnosis is difficult the x ray findings being very similar to those of a benign duodenal ulcer.

3 The vegetative type shows a gigantic bulb with an irregular filling defect and numerous intersecting lines of an irregular pattern. A niche, proof of its tendency to ulcerate may be seen at times.

Dilatation of the bulb may be caused also by sarcomas. According to Stammer these may be

1 Parietal sarcomas pedunculated or not and internal or external sarcomas. The internal ones may cause the same defect as that caused by a polyp. The external ones may become very large and cause compression (the myosarcoma of Sallis was the size of a baby's head).

2 Intramural sarcomas circumscribed or diffused and unless very extensive may be very difficult to diagnose.

The sarcomas are lymphosarcomas.

JOSEPH M. A. PAXE, M.D.

Study of the Gall Bladder in Obstructive Jaundice by Means of Diagnostic Pneumoperitoneum (Studio delle colecisti negli itteri da occlusione mediante pneumoperitoneo diagnostico) ANTONIO LURA and AXILE VIVARELLI. *Radiol. med.*, Milano 1947 33 633.

Cholecystography is either contraindicated in obstructive jaundice or fails to furnish sufficient

metabolic protection of the detoxifying organ by preventing its glycogenolysis. These possibilities need further experimental exploration which is now in progress.

MARY FRANKLIN FOR, M.D.

Endotracheal Anesthesia for Operations on Cleft Lip and Cleft Palate M. D. LEICK and H. A. KESTER. *Anesthetist* 27 1945, 9 32.

Some modifications of the usual endotracheal technique are used by the authors in anesthesia on children of less than a year old. Beyond that age the technique is not materially different from that in common use (Adrian's child circle filter technique).

Premedication is somewhat unusual in that morphine and scopolamine are used in patients of any age. This has been the practice of the authors in more than half of their series of cases, over a period of 7 years; however no dosage table is included.

Induction of anesthesia is accomplished with diethyl ether followed by diethyl ether both given by open drop. Very early use of an oral oropharyngeal airway is advocated to prevent obstruction by the tongue falling into the cleft in the palate.

Intubation is done in the second plane of stage 3 care being taken to flood the lungs with oxygen under the mask just before intubation. The patient's head is elevated on a padded ring which enhances stability of the head and flexes the neck on the shoulders. The authors use their own modification of the laryngoscope with a wide blade narrowed antero-posterior diameter and a bend upward of the blade at its tip. The width of the blade aids in preventing the end of the instrument from dropping into the cleft in the palate.

A soft rubber or vinyl plastic Magill tube lubricated with water soluble nupercaine jelly is used.

Abduction of adducted cords may be obtained by blowing down a tube whose tip is placed at the glottis. The pharynx is then sucked off. The authors offer comparisons and recommendations on the sizes and lengths of tubes used. Oral endotracheal tubes are long enough to reach from the lobe of the ear to the tip of the nose with 1 to 2 cm. to spare. No cuff is used on the tube as the cords soon accommodate to the tube and no anesthetic mixture is lost.

Maintenance is accomplished with an apparatus consisting of an "endotracheal tube, a metal connector with a bore the same size as the tube, a short piece of rubber tubing, the metal piece containing the inhalation and exhalation valve (Lefgh valve), a 1 liter reservoir bag, and a rubber tube leading to the gas feed. Nitrous oxide and oxygen are supplied if necessary ether or cyclopropane is added for depth. The technique described was used in 54 per cent of the cases and Ayer's technique was used in 9 per cent.

Blood loss is replaced as it occurs, through a venous cut-down. Complications in induction are those of any open drop anesthetic. Endobronchial intubation is the most serious maintenance complication and accounted for one death. If rapid, deep respirations threaten to lead to collapse of the patient, double the premedication dose of morphine is given intravenously. Postoperative complications center about maintenance of the airway in an infant previously accustomed to more airway space than he now has.

Of the 493 patients whose cases are reported, 57 per cent were 3 years of age or under. Three deaths occurred: one from bronchial intubation, one from shock, and one from transfusion of incompatible blood.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

The Association of Achalasia of the Cardia with Esophageal Carcinoma. P. BAEK and K. SIEGHER
Brit. J. Radiol. 1947 20 528.

The association of carcinoma of the esophagus with cardiospasm or achalasia is not well recognized. The authors have found in the literature 8 such cases in which the clinical data were adequately included and 9 cases in which the clinical details were not available because of the wartime disposal of medical libraries. To these they added one case.

All of the tumors were located in the midesophagus (dilated portion) and nearly all were squamous cell carcinomas. The average age was 54.9 years and 89 per cent of the patients were males. The average lapse of time from the onset of achalasia until the carcinoma was identified was 19.3 years, and the symptom free interval after treatment of the achalasia was 7 years.

Because the tumor develops in the dilated esophagus marked obstructive symptoms do not appear even though the tumor may be quite large.

Roentgen diagnosis is difficult not only because the elongated tortuous esophagus may be filled with food, but the demonstration of achalasia may be taken as an adequate explanation of the symptoms of the patient and the carcinoma may be overlooked. Loss of weight which is out of proportion to the duration of the symptoms of achalasia and the presence of blood tinged vomitus however are signs which are very suggestive of carcinoma.

The authors believe that achalasia produces conditions which are favorable to the development of carcinoma.

ROBERT BURNS LEWIS, M.D.

Special Roentgenographic Aspect that May Be Assumed by Primary Carcinoma of the First Part of the Duodenum (Sul particolare aspetto radiologico che possono assumere i canceri primitivi della prima porzione duodenale). DIONISIO BREDATI
Arch. ital. mal. app. diger. 1947 13 353.

A short discussion of the difficulty in diagnosing malignancy of the duodenum is followed by the report of a case in which the diagnosis of carcinoma of the first part of the duodenum was made roentgenologically before operation and confirmed by surgical intervention. This is of great interest because (1) the precise location of the tumor was determined and (2) the neoplasm was diagnosed as a primary one in the first part of the duodenum.

The case could have been easily diagnosed as a primary tumor of a contiguous organ: a polyp of the stomach or duodenum or as a gastroduodenal invagination but the increase in size and the rigidity of the duodenal bulb with its filiform channeling conveyed the idea that the tumor was primary in this part of the intestinal tract.

Cancer of the duodenum because of the annular arrangement of the submucous lymphatics assumes a circular pattern. Viewed from within the lumen the neoplasm appears like a rigid valve ulcerated at times. When the tumor is located near the genu superior of the duodenum it will cause an enlargement of the bulbous portion which at times may approach a gigantic size. When the neoplasm is located near the pylorus the stomach is the part to become dilated the duodenal bulb appearing like a rigid canal.

The polypoid type has a tendency to ulcerate. There is however a malignant ulcerative type annular in shape which involves from one half to three fourths of the circumference of the viscus. It has a hard base, the edges are raised and the growth bleeds easily. The serosal aspect of the bulb may appear normal or the bulb may be impregnated with cicatricial tissue when the ulcer is small. This type has been diagnosed as an ulcer by both the radiologist and the operating surgeon.

The roentgenographic findings are:

- 1 In the annular type there is a more or less serrated stenosis. When the growth is juxtapiyloric there will be pyloric stenosis and when involving the genu superior of the duodenum the bulb will be markedly dilated and later will involve the pylorus and stomach. The diagnosis in these cases is difficult. A partial stenosis changes the duodenal bulb to an irregular small somewhat tortuous channel.

- 2 In the ulcerative type the diagnosis is difficult, the x ray findings being very similar to those of a benign duodenal ulcer.

- 3 The vegetative type shows a gigantic bulb with an irregular filling defect and numerous intersecting lines of an irregular pattern. A niche proof of its tendency to ulcerate may be seen at times.

Dilatation of the bulb may be caused also by sarcomas. According to Stammer these may be:

- 1 Parietal sarcomas pedunculated or not and internal or external sarcomas. The internal ones may cause the same defect as that caused by a polyp. The external ones may become very large and cause compression (the myosarcoma of Salis was the size of a baby's head).

- 2 Intramural sarcomas circumscribed or diffused and unless very extensive may be very difficult to diagnose.

The sarcomas are lymphosarcomas.

JOSEPH M. A. PAPP, M.D.

Study of the Gall Bladder in Obstructive Jaundice by Means of Diagnostic Pneumoperitoneum (Studio delle colecisti negli itteri da occlusione mediante pneumoperitoneo diagnostico). ANTONIO LURA and AXIL VIVARELLI. *Radiol. med.*, Milano 1947 33 633.

Cholecystography is either contraindicated in obstructive jaundice or fails to furnish sufficient

information. In such instances pneumoperitoneum renders good services because it allows the study of the location, size, morphologic aspect of the gall bladder and demonstrates its relations to the adjoining organs. With the application of Courvoisier's law an occlusion of the gall bladder by a calculus can be differentiated from a malignancy.

The study can be done with the patient in one of the following 3 positions: (1) upright, (2) supine, with roentgenograms taken in the postero-anterior direction and (3) recumbent position, with roentgenograms taken in lateral direction. Modifications of the position can be advantageously employed according to individual requirements.

A gall bladder nearly completely hidden under the liver cannot be easily differentiated from Riedel's lobe. Excessive weight of the patient or close apposition of the liver to the right kidney, duodenum or the transverse colon may also interfere with the visualization of the gall bladder.

The author recommends the following positions:

1. Reverse Trendelenburg—roentgenograms to be taken in the dorsoventral direction. The degree of the optimal inclination of the table should be determined by means of a fluoroscopic examination. The patient lies on the table in supine position.

2. Left semilateral prone position—the x-rays to be directed from the right flank toward the front. This technique is especially recommended for cases in which the gall bladder is adherent to the parietal peritoneum. Pneumoperitoneum may be supplemented in selected cases by the administration of barium per os.

In 35 cases the pneumoperitoneum rendered valuable services in regard to the diagnosis.

JOSEPH K. NARAY, M.D.

Intracranial Angiography via the Vertebral Artery. SNO RADDER. *Acta radiol.* Stockh., 947 23, 338.

The author describes a technique which may be used for vertebral angiography. A ureteral catheter is introduced via the radial artery. The radial artery is exposed and ligated distally in the wound, and a tourniquet is applied proximally. A small cut is then made in the vessel and the catheter is inserted. The tourniquet is removed and the catheter is gradually introduced under fluoroscopic guidance. When the catheter has entered the vertebral artery 10 c.c. of 35 per cent diodrast solution are injected and suitable roentgenograms are taken.

Following removal of the catheter the radial artery is ligated. No palpable difference has been noted in the radial pulse at the wrist after ligation.

Thus far the method has been used in only a few cases.

C. R. PERRYMAN, M.D.

Roentgen Therapy in Melanoblastoma (La pleuro-roentgentherapie bei melanoblastom). FRANCESCO SANTAGATI. *Radiol. med.*, Milano, 947 35, 337.

Thirty-eight cases of melanoma treated in the Radiology Institute of Milan were received and classified according to the method of therapy.

The first group consisted of 14 patients treated by roentgen therapy alone; of these, 9 were cured for time intervals varying from 1 to 5 years; 2 were not followed up and 3 showed evidence of metastases in 1 to 3 years.

The second group consisted of 3 patients who were treated surgically. In this group evidence of recurrence at the site of operation necessitated subsequent irradiation which resulted in cure in the 2 subjects in whom metastases had not developed, at an interval of 6 years.

The third group included 7 patients treated with radium only. Although the lesions in this group were on the whole, somewhat more advanced, only 1 instance of metastases was noted. Of these, 4 were cured for time intervals varying from 14 months to more than 3 years.

In the fourth group were 14 patients treated by surgery with subsequent application of radium. Of this series 4 showed metastases. Of the 14, 6 were well at 3 years or less, while the others showed recurrence or were lost to the clinic.

The results obtained in these cases suggest that irradiation can be successfully employed in the treatment of these tumors, and that surgery should be used only when irradiation is impracticable.

RADIUM

The Treatment of Cavernous Hemangiomas in Young Infants (Le traitement des angiomes caverneux des jeunes enfants). SMOORE LAMORDE. *Acta radiol.* Stockh., 947 23, 7, 3.

The author reports the results of radiation therapy in 315 young infants and children with cavernous hemangioma. Both large and small hemangiomas and portwine birthmarks were treated. The report is one of impressions rather than of statistics.

Lamorde believes that the treatment may be initiated in early infancy having started it in infants at the age of a few months. His patients were treated by radiation alone. All forms of irradiation were employed but in general he preferred the use of either the radium element or radium emanation. In some instances removable radium seeds were employed. These were especially useful in the large cavernous types of hemangioma. The author preferred the use of minimal doses, either in flat enamel containers or needles containing 1 or 2 mgr. of radium with 0.5 mm. of platinum filtration. The beta rays are the most important.

The use of very small doses avoids most of the complications, such as actinic ulceration, disturbances of growth at the epiphyseal lines, or depressions of the flat bones even epilation was avoided. These doses may be repeated at intervals of 3 to 4 months. It is often noted that the lesion will regress for quite a few months, and it may take even years to disappear completely.

In this series no other methods of therapy were employed. The results have been eminently satis-

factory from both a therapeutic and cosmetic standpoint. Except for the ulcerated angiomata which always leave a scar, esthetic results have been the rule rather than the exception. The illustrations confirm these opinions. WILLIAM C. BECK, M.D.

Some Complicating Factors in the Radium Treatment of Carcinoma of the Cervix Uteri. GILBERT STRACHAN *Acta radiol.*, Stockh. 1947 28 545

There are five conditions which are the main contraindications to the insertion of radium in the treatment of carcinoma of the cervix. These are: (1) advanced emaciation and cachexia, (2) extensive anemia, (3) inflammatory pelvic lesions, (4) an extreme degree of pelvic extension, and (5) fistula formation. The anemia and inflammatory pelvic lesions are temporary but should be corrected before the radium is inserted. The red blood count should not be below 3 million cells and the hemoglobin not below 40 per cent. This can be corrected by bed rest, nourishment, and blood transfusions. The present-day use of penicillin has been very effective in the treatment of inflammatory pelvic lesions. These include parametritis, peritonitis, pyometria, salpingitis, pyosalpinx, and pelvic abscess. Pyometria is particularly deceptive and difficult to diagnose. It should be cleared up before the radium is inserted. Occasionally the emaciation and the cachexia can be improved, but if it is not, the insertion of the radium may hasten the fatal results. The author believes that an occasional case of rectovaginal fistula can be benefited by means of radium treatment, but that vesicovaginal fistulas are aggravated by it.

The cervical canal may sometimes be very difficult to find and may very often be toward the periphery of the mass. Great care must be used in probing for this canal as trauma to this region is a very important cause of pelvic inflammatory disease. Postoperative complications are relatively rare but are often associated with poor or faulty technique. Most frequently they are observed as irritant effects to the adjacent bladder, rectum, or vagina. Packing the bladder and rectum out of the field with gauze will reduce the incidence of these complications markedly. Other important postoperative complications include pelvic infection, postoperative pyometria, fistulas (rectovaginal, vesicovaginal, or both), intestinal obstruction, and rectal and urethral stricture formations. Pyometria is most common in patients over 50 years of age. Pelvic infection was frequently associated with considerable probing to find the uterine os. The majority of the fistulas occurred in stage 3 cases. The primary mortality from the insertion of the radium was 2.6 per cent in the author's series of cases at Cardiff Royal Infirmary, England.

To evaluate the risk to the patient and to determine the presence of contraindicating factors, particularly those which are amenable to treatment, it is necessary to do a thorough examination of the patient, and this should be done by experienced and well-trained specialists. S. A. PATTERSON, M.D.

The Results of the Treatment of Carcinoma of the Uterine Cervix in the Radiologic Institute of Helsinki in the Years from 1937 to 1942 (Ueber die Behandlungsergebnisse der Kollumkarzinome im Strahlenbehandlungsinstitut zu Helsinki aus den Jahren 1937-42). V. KAHANPÄÄ and J. O. KANKKURIN *Acta radiol.* Stockh. 1947 28 519

The authors review the results in 524 patients with carcinoma of the cervix treated by radiation alone for over a 5 year period. Only 35 per cent of these were considered to be in a favorable stage for this type of therapy. Many patients with early conditions were subjected to operative therapy, and many patients were sent to the institute for palliative therapy because nothing else could be done for them. The former are not included in this report. The series is also not a perfect one as it was collected during the war years and some of the therapy had to be hurried or stopped because of the exigencies of war. For a time the clinic had to be completely cleared to permit repair of bomb damage.

Nevertheless, the average time of the appearance of the patient in the clinic from the time of the first abnormal bleeding was 6.2 months. The time lag between the patient's first consultation with a physician and her appearance for therapy was 1.3 months. The author blames the late visit of the patient to her physician on the indolence of the patient and her disrespect for the obvious symptoms. In 58 patients of this series (11.1%) the condition was completely hopeless and not treated either because of the extent of the growth, the poor condition presented by the patient, or the presence of distant metastases.

The therapy usually consisted of radium so placed as to irradiate both the uterine cervix and the vagina. In patients in whom the vagina was roomy and the rectum could be packed well out of the way, the vaginal doses were greatest. In some cases a lead plate was employed to protect the rectum. The average treatment consisted of 3,300 millicuries to the uterus and 4,700 millicuries to the vagina. A total irradiation dose of 8,000 millicuries was given. This was followed immediately by roentgen ray irradiation of the parametrium with 2,400 roentgen units as the depth dose. This was applied through two anterior and two posterolateral portals. The radiation was stopped if there was a marked rise in fever. The complication of a moderate proctitis with diarrhea and some blood was frequent, but rectovaginal fistula was rare.

All of the cases were studied histologically. Of the 466 patients, 167, or 35.8 per cent, were alive at the end of 5 years. The percentage of 5 year cures was in direct relationship to the clinical stage of the carcinoma: that is, 88 per cent of those with carcinoma classed as grade 1 were alive at that time, while only 6 per cent of those with carcinoma classed as grade 4 were alive. On the other hand, there did not appear to be any relationship between the histological classification and the percentage of cures.

WILLIAM C. BECK, M.D.

The Experiences with Radiotherapy in Cancer of the Cervix and of the Corpus of the Uterus at the Radium Center in Odense. P. JACOVY *Acta radiol. Stockh.*, 947 28 505.

The results of radiological treatment of cancer of the cervix and cancer of the body of the uterus at Radium Center in Odense, from 1938 to 1941, are presented and analyzed. The results obtained are grouped according to the League of Nations criteria. Three hundred and seventy three patients with cancer of the cervix were examined and 365 patients received treatment. Of these, 120 patients were free from evidence of the disease after a period of 5 years with an absolute cure rate of 32.2 per cent and a relative cure rate of 39 per cent. All of the patients received external roentgen therapy in addition to the radium treatment.

Since 1938 the procedure has been to complete roentgen therapy before radium is applied and it is the author's opinion that this manner of treatment has proved to be a very valuable refinement of the technique. At the same time the responsibility for the roentgen treatment was shifted from the surgeon to the radiologist. As a result of one or both of these factors the percentage of 5 year cures was considerably greater after 1938 particularly of lesions in stages 3 and 4. The primary mortality in the total series was 11 per cent. In 11 per cent of the cases, bladder and rectal reactions such as fistula, were

encountered in from 1 to 5 years following treatment, but in only 11 per cent of the cases were these of a permanent nature. The intensity of radium treatment was 6,000 to 7,000 mgm. hr. The average dose to the parametrium from external therapy averaged between 2,000 and 2,500 roentgens.

Cancer of the body of the uterus was divided into three categories according to Heyman's grouping, viz. (1) clinically operable lesions (2) technically operable lesions, but had risks because of other reasons such as obesity of the patient, old age or associated disease and (3) inoperable lesions. It is noted that all cases of carcinoma of the cervix, in Denmark are referred to radiological treatment, but that there is no definite policy concerning treatment of cancer of the body of the uterus. Some patients are treated surgically (if the lesion is in the operable category) while others are treated radiologically. Before 1940 the radiological treatment of cancer of the body of the uterus was nearly the same as that for carcinoma of the cervix but since 1940 the packing treatment of Heyman has been used. The results obtained with the later treatment were definitely superior. The author notes that treatment of the operable lesions with radium gave equally as good results as treatment by surgery. The results of radiological treatment were much better in the clinically operable group than in the other two groups.

S. A. PATTERSON M.D.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Diagnosis of the Thrombopenic Purpura. Study of the Megakaryocytes of the Sternal Marrow Thrombopenias of the Menopause (Diagnostic des purpuras thrombopéniques. Étude des mégakaryocytes de la moelle sternale: thrombopénies de la ménopause) BERNARD DREYFUS and J. P. SOULIER. *Rev hemat* 1947 2 303

It is often difficult to distinguish between the idiopathic thrombopenias and those secondary to the action of chemical or physical agents. Etiologic, clinical and hematologic data allow differentiating them, but not always and the myelogram should be of great help.

The normal megakaryocyte rate and the physiologic equilibrium of young adult degenerated and platelet forming megakaryocytes are variably given by different investigators. Therefore, the authors have first studied eight normal myelograms. The rates ranged from 150 to 600 megakaryocytes per million nucleated cells. There was a certain parallelism between the megakaryocyte rate and the percentage of young and platelet forming varieties of megakaryocytes. A normal slide may not contain megakaryocytes with platelets.

The megakaryocyte series presents remarkable peculiarities in idiopathic thrombopenia of which 9 cases are considered: at least 5 cases were genodystrophic purpuras. Megakaryocyte hyperplasia is the rule; the normal number of these cells is increased three, five, and sometimes tenfold so that in some cases the diagnosis is suggested as soon as a slide is examined under low magnification. The absence of megakaryocytes with platelet formation is no less remarkable. A high percentage of young forms is usual but is not surprising in megakaryocytic hyperplasia. The number of degenerated megakaryocytes seems to be below normal. There is usually an asynchronism between a completed nuclear maturation and a young intensely basophil cytoplasm.

The myelogram of secondary thrombopenia of which eight slides have been studied may present three types. The first two types cannot be confused with the picture of primary thrombopenia, whether there is a hypoplasia or aplasia with rarefaction or even disappearance of the megakaryocytes or the appearance is that of a normal slide. The third type is rather deceptive because of the normal number of megakaryocytes and the absence of megakaryocytes with platelet formation. However the paradoxical hyperplasia so characteristic of primary thrombopenia is usually absent. The determination of the percentage of young and degenerated forms is of little usefulness. The finding of intense megakaryocyte macrophagy is perhaps a sign of infectious purpura. Decidedly evolutive changes militate in favor of secondary thrombopenia.

The data of the myelogram alone allow a classification of the thrombopenias into those of myeloid origin (those due to a defect of elaboration and those due to a disturbance of the megakaryocyte maturation) and those of peripheral type, due to capillary accumulation or excessive splenic destruction but without myeloid lesion. The medullary localization of the disturbance in the formation of platelets does not exclude a splenic causation.

The clinical facts suggest the possibility of dividing the idiopathic thrombopenias into the constitutional (dysthetic and genodystrophic, the latter being subject to splenectomy) and the acquired, which include a rather peculiar type—the thrombopenias of the menopause, which are represented by 2 observations.

RICHARD KEMEL, M.D.

The Surgical Treatment of Pressure Sores, STUART GORDON. *Plast Reconstr Surg*, 1947 2 557

Efforts directed at making the paraplegic patient ambulant have brought the problem of the treatment of pressure sores to the fore. While the removal of pressure together with good nursing will usually result in healing, the time taken is long and when the sores are healed the covering is unstable. A few free grafts were tried but their use was quickly abandoned. This led to the consideration of pedicle grafting. It soon became obvious that the best type of pedicle graft was a large local rotation flap so planned that there was a minimum of scar over the pressure points.

Patients selected for operation are those in whom invasive infection is absent, whose blood urea is within normal limits, whose hemoglobin level is satisfactory, whose appetite is good and whose serum protein level is normal. Occasionally closure of a pressure sore must be done when conditions are not ideal. Thus, the actual blood protein level may be abnormally low, the patient steadily losing ground. In such a case successful closure of the pressure sore will abruptly stop the constant loss of protein and will, in fact, be a life-saving measure.

At first the author attempted to operate on paraplegic patients without anesthesia, but the patients developed pallor, sweating, nausea, vomiting, lowered blood pressure and a fast pulse. The authors have now made it a routine practice to give these patients a general anesthetic.

Fifty operations have been done on 27 patients. A large rotation flap was used to cover the raw area left after excision of the pressure sore in 46 instances, a V-Y advancement in one, a Z-plastic shift in 2 patients and multiple local flaps in 1 patient. Primary healing was obtained in 31 instances, slight separation in 13 and marked separation in 6. Even though satisfactory healing occurred in 48 patients, free grafts to close the donor sites of flaps are rarely needed.

LOUIS T. BYARS, M.D.

A Case of Glomus Tumor with Primary Involvement of Bone RAFAEL LATTES and DAVID C. BULL. *Ann Surg* 1948, 127: 87

The authors report a case of glomus tumor because of its unusual location. The patient was a 28 year old white woman whose chief complaint was pain in the right thumb of 4 years duration. The thumb was enlarged with thickened and discolored skin and vesicles on the volar surface. Roentgenograms showed honeycombed areas of decalcification in the distal phalanx. At operation the terminal phalanx of the thumb was found to be almost completely replaced by areas of softening containing a jellylike material. The lesion was curetted, the defect filled with a bone graft, and the patient had no further symptoms. Microscopic examination revealed typical histological features of a glomus tumor with spindle shaped glomus cells, epithelioid elements, and smooth muscle cells.

The writers believe this is only the second case report of a glomus tumor completely encased in bone. However many cases have been reported of glomus tumors which occurred in places other than the cutaneous-subcutaneous junction where normal glomera are usually found. These cases can be explained by assuming the existence of normal glomera sparsely distributed anywhere in the body or by considering the glomus tumor a highly differentiated and specialized variety of hemangiopericytoma. It is probable that both the glomus cell and the pericyte represent modified smooth muscle elements from blood vessel walls and that both descend from a common undifferentiated stem cell. It is conceivable that a neoplasm arising from such a stem cell might differentiate into a glomus tumor even in a region where glomera are not normally found.

S. LEON TETELMAN, M.D.

The Changing Cancer Death Rates. EVELYN A. POTTER. *Cancer Res* 1947 7: 35

In epidemiological studies of cancer consideration of both tumor origin and pathologic histology is essential to avoid the fallacies inherent in mixed classifications. At present however the cellular variations are not listed in the vital statistics reports. To secure a correct picture of changes in mortality an adjustment of crude death rates is necessary because of the effect of a changing age composition in the population.

This presentation concerns itself with studying cancer data by the site of origin. The adjusted rate for each of the 22 sites studied was allocated to one of three classes depending on whether the adjusted rate showed an upward trend, a downward trend, or no significant trend.

The class showing upward trends included cancers of the pancreas, testes, prostate, intestines, lung, pharynx, larynx (male), other respiratory organs, ovary, rectum (male), and kidney (male). This was considered, at least in part to be due to a higher accuracy in diagnosis. Cancers of the lungs, other respiratory organs, and pharynx revealed the great

est increase possibly as a result also of an increase of respiratory irritating agents.

In the class exhibiting no significant trend were cancers of the larynx (female), vulva, vagina, breast, scrotum, bladder, esophagus, kidney (female), and rectum (female). The adjusted rates for most of these sites were small, the principal exception being cancer of the breast (female). The latter however doubtlessly belongs with the sites having declining rates since many cases, which had metastasized, were formerly mistaken for and classified as primary cancer of the liver, a disease which is found to have decreased.

Cancers of the stomach, buccal cavity, skin, uterus, and liver showed an appreciable downward trend. Education and improved therapy probably played leading roles in this reduction. Better obstetrical care and the declining birth rate were also considered to be significant factors in cancer of the uterus. The relationship between childbearing and cancer of the uterus has been well established.

However the decrease that has occurred in the mortality from gastric cancer is far greater than could be expected to result from the general educational programs and from improved medical service. The author speculates that this improvement is probably due to better dietary and living conditions.

When the cancer death rates of the white population for 1933 to 1944 in the Continental United States were adjusted to the age distribution of the total population of the United States, as enumerated in the census of 1930, the annual average increase in the rate for males was 0.76 per cent, while that for females decreased 0.38 per cent annually.

DAVID H. LYNN, M.D.

DUCTLESS GLANDS

Anatomic and Clinical Study of Spontaneous Parathyroid Tetany in the Adult. Symptomatic Importance of Radiologic Parathyroid Calcifications. (Étude anatomique-clinique des tétanies parathyroïdiennes spontanées de l'adulte. Valeur symptomatique des calcifications parathyroïdiennes radiologiques.) M. LIGERAT and R. BERTHE. *Ann endocr* Par 1947 8: 17

The authors discuss 7 cases of tetany of parathyroid origin in adults. One case was of their own observation, the others were reported in the literature.

Histologic studies of parathyroid glands in cases of tetany in infants as well as in adults show that the causative lesion may be hemorrhage, tuberculosis, amyloidosis, or syphilis. Of these, hemorrhage, either minute or large, seems to be the most frequent occurrence.

The authors discuss in detail the normal and pathologic anatomy and histology of the thyroid and parathyroid glands, and stress the difficulties which sometimes arise in differentiating parathyroid tissue from a colloid vesicle of thyroid tissue or a toxic adenoma. Even experienced surgeons have mis-

taken one for the other in biopsies or in removal for therapeutic purposes. These difficulties are even greater in cases of pathology of the thyroid and parathyroid, especially in tuberculosis in which the characteristic structure of the parenchyma is more or less destroyed.

Attention is drawn to a fact which has not been described before: there are small areas of calcification in the diseased glands, mostly located at the capsule and irradiating into the thyroid tissue. These calcifications can be demonstrated with x rays and, in certain cases, may be helpful in establishing the diagnosis.

The occurrence of spontaneous parathyroid tetany in adults seems to be extremely rare as the authors found only 6 cases reported in the entire literature since 1903. WERNER M. SOLMITZ, M.D.

SURGICAL PATHOLOGY AND DIAGNOSIS

The Role of the Spleen in Relation to Cutaneous Wound Healing (*Mifla e potere di riparazione delle ferite cutanee*) MARIO PELLOJA. *Arch. ital. chir.* 1947 69 128.

The author studied the influence of splenectomy or ligation of the splenic artery on cutaneous wound healing.

Seven groups of animals were used experimentally. A dorsal cutaneous wound was made in each animal. The first group was the control group in which only the dorsal cutaneous incision was made. It took 1 month for scar formation, and from 11 to 12 days for a 30 per cent reduction of the size of the wound to take place.

In the second group a laparotomy was performed in addition to the cutaneous wound made on the dorsum as in the control group.

Splenectomy was performed in the third group. Ligation of the splenic artery was carried out in the fourth group. In the fifth group the dorsal wound was made 15 or 20 days after the laparotomy. The dorsal wound was made 15 or 20 days after splenectomy in the sixth group and in the last group the dorsal wound was made 15 or 20 days after the splenic artery was ligated. The following results were obtained:

In the second group the wound was reduced 9.2 mm. per day; in the third group the wound was reduced 6.8 mm. per day; in the fourth group the reduction was 6.7 mm. per day; in the fifth group it was 13 mm. per day; in the sixth group 15 mm. per day; and in the last group the reduction was 11 mm. per day.

The experiments show that healing is retarded following intervention in contrast to cases in which the wound was made from 15 to 20 days after the intervention in which healing was faster than in the control animals. On the basis of these experiments, the author doubts the existence of a real specific function of the spleen to regulate cutaneous scarification; however, he attributes the changes to the general repercussion of the operative trauma.

The author has seen the greatest velocity of cicatrization from the fourth to the twelfth day while the average velocity was 11.5 mm. daily.

ARTHUR F. CIPOLLA, M.D.

A Technique of Dissociation and Measurement of the Principal Physicochemical Factors of Blood Sedimentation (*Une technique de dissociation et de mesure des principaux facteurs physico-chimiques de la sédimentation sanguine*) M. F. JAYLE and J. BADIN. *Rev. hémat.* 1947 2 183.

The sedimentation speed of the red cells as obtained by the method of Westergren is the result of several variable factors, all of which do not have the same physiopathologic significance. Therefore the authors have worked out a relatively simple method for the separate study of the three kinds of factors which condition this speed: (1) the red cell factor which includes the number of cells, their average weight and other individual factors; their tendency to reversible aggregation (Frimberger factor) and their exponential distribution conditioned by the more or less marked heterogeneity of the cell aggregations and of the cells themselves; (2) the plasma factor (fibrinogen considered from the qualitative and quantitative points of view) and (3) the serum factor which is complex and in which must be considered the rate of certain alpha globulins of glycoprotein nature, particularly haptoglobin.

The following figures represent the averages obtained from the blood of 10 normal young women:

Hourly sedimentation speed in vertical tube	6 mm
Number of red cells (height of sediment	
24 hours in inclined tube x 3)	4,558,000
Sedimentation speed in saline solution	25
Factor of Frimberger	30
Sedimentation exponential	15 for 6 mm.
Serum factor	14
Plasma factor	23

The averages obtained from the blood of 5 normal young men seemed to differ from those found in normal young women only in the number of red cells which was 5,300,000.

The causes of error connected with the technique are the variations in temperature which seem to be particularly serious for sedimentation in the inclined tube, the variations in the number of red cells due to the use of an incorrect amount of cell mass washed in the various mixtures, the presence of air bubbles clinging to the cell aggregations, the qualitative differences between the arabic gums of different origins, the alteration occurring in the gum solution as it becomes older, the isotonicity and approximate neutrality of the saline solution and the difficulty of certain readings because some bloods behave like heterogeneous suspensions and the upper limit of their column is difficult to ascertain although under good lighting and with some training it is nearly always possible to obtain a reading 95 per cent correct.

The authors demonstrate the clinical interest of their method by 3 examples in which the patients

presented an hourly sedimentation speed of about 60 mm. in critical tubes and would have been considered previously as having the same physiologic disturbance. In reality the new method shows that the acceleration of the sedimentation is due principally to hypoglobulia and secondarily to the fibrinogen in the first patient, principally to the serum factor and to fibrinogen in the second and nearly exclusively to the fibrinogen in the third. This already suggests a differential diagnosis. In fact, the first woman had had a serious hemorrhage after delivery, the second had a beginning phlebitis, and the third woman had a normal pregnancy at term with its normal hyperfibrinemia of 5 gm.

RICHARD KEMEL, M.D.

Some Effects of Experimental Thermal Burns on Vascular Endothelium Employing a Perfusion Technique in Anesthetized Dogs. TADGE C. CRISHOLM and ETTIE HARDENBERGH. *A. Surg.* 943, 7-15

The authors report a method for perfusing the vascular tree of the hind leg of an anesthetized dog with a hot solution of 6 per cent gum acacia in normal saline solution in order to study the injury to the vascular endothelium. They label conventional methods for producing experimental burns as relatively crude insofar as they affect many vital structures simultaneously and unselectively.

The experimental technique is carefully described. Periods of observation following perfusion ranged from 4 to 36 hours. Font volume lymph flow lymph protein concentration, temperature of the animal, arterial blood pressure, pulse and respiration, blood hematocrit, photographs of the hind legs and skin temperature on the hind feet were noted. Also selected skin biopsies, exploration of the perfused vessels and controls, and microscopic study of selected vessels were made.

Local dissection and the application of a tourniquet did not contribute to changes in vascular permeability with subsequent swelling of the extremities in the control animals. Perfused legs, however, showed edema, increase in lymph flow and changes in lymph protein content. Anoxia attendant on perfusion apparently did not contribute significantly to these results. When the rate of flow was brisk and the period of flow not too prolonged the incidence and magnitude of swelling was in direct relation to the temperature of the perfusate. When the perfused solution entered at 36° C. changes were meager and readily reversible, but at 75° C. the changes were severe and progressive.

Microscopic examination of skin biopsy specimens from swollen feet of animals perfused with solutions heated above 60° C. or beyond 10 minutes of perfusion time showed subcutaneous edema, congested capillaries, dilated lymphatics, and extravasation of the red cells into the intercellular spaces. The endothelial coat of veins from such legs showed a disruption of the geometric endothelial pattern with fragmentation and disappearance of the lining cells.

Under these experimental conditions, there was no evidence of the existence of immediate shock, nor was any answer found to the question whether hemocoagulation results from release of toxic substances or a shift in body fluids. Neither bacteria nor their toxins contributed to the findings, although no animal was studied longer than 36 hours.

Experimental data indicated that the duration and rate of flow of the perfusion play a role in altering the permeability of the vascular endothelium as judged by the incidence of leg swelling, rate of lymph flow and alterations of lymph constituents.

EXPERIMENTAL SURGERY

Experimental and Clinical Studies of Reduced Temperatures in Injury and Repair in Man. Structure and Potentialities of Human Skin in Temperature Control and in Defense against Thermal Trauma. HAMILTON BAXTER and MARTIN A. ERTM. *Plast. Reconstruct. Surg.* 1947 2, 369.

The understanding of the reaction of human tissue to reduced temperatures of various degrees of severity is becoming more urgent in recent years. Modern warfare subjects large numbers of individuals to the influence of either prolonged moderate cold, as in immersion foot suffered by shipwrecked mariners, trench foot prevailing among the infantry personnel, or to the action of severe cold as in high altitude flying. The casualties due to cold have been particularly large in the American, German, and Russian armies of World War II.

Studies of the limit of endurance of army personnel under the influence of low temperatures are in progress in northern territories. Elective refrigeration has had many advocates for the purpose of anesthesia and as a means of treatment of gangrene and other vascular disorders. Moreover being a "thermal injury" understanding of the pathogenesis of injury by cold and the study of the reaction of human tissue to various degrees of reduced temperature should also throw some light upon the problem of burns and other allied types of trauma.

The purpose of this investigation was to study the direct effect of a sequence of cold temperatures on the human tissues (skin grafts) free of vascular and nerve elements and subsequent correlation of these observations with (a) the effect of cold on normal intact skin (b) the effect of cold on healing and freshly healed surfaces all under controlled conditions, and (c) with the findings in actual clinical cases. It was hoped that a better understanding of the pathogenesis of injury by cold, the effect of cold on wound healing, and a more effective approach to treatment would result.

Human tissues thrive best at the temperature of 98° to 99° F. (37°C.) and this is the level at which the balance of heat production and heat loss is maintained.

The existence of a special organ makes regulation of body temperature and adaptation of the human

body to variations of environment more effective. This organ is the skin.

Exposure of living tissue to different temperatures produces alterations in the rate of metabolic processes commensurate with the effect on the rate of chemical reaction and enzyme action.

It is conceivable that cold may damage the cell sufficiently to cause a disintegration of the cell membrane, yet not completely destroy the enzymes thus released. Such enzymes could act upon the distant unaffected cells by coming in contact with them when the normal temperature is restored.

When a portion of the human body is locally chilled or frozen, there results a gradation of temperatures which may range from a very low level at the surface of the skin (If carbon dioxide snow was used for example, through the different levels of temperatures until normal body temperature is reached at some distance from the skin surface the metabolic alteration will be proportional to the temperature at a particular level and will prevail only as long as the temperatures are maintained but the destruction of the integrity of cells and sequelae of the physico-chemical alterations of living matter may become apparent only after a lapse of time.

In view of the previously considered factors it becomes imperative to carry out investigations and observations under conditions in which the interplay of the various factors is known or can be determined at all times, and compatible controls are constantly available. Such a set up has not been invariably obtained but the authors have attempted to get as near as possible to it. They chose dermatome donor sites (areas from which a uniform thickness of skin had been removed with the Padgett Hood dermatome) on the thigh as the standard area. Fresh dermatome donor sites have several features which make them particularly suitable for the study of the influence of a specific factor on wound healing.

The range of the temperatures studied and the details of the methods of cooling will be incorporated in a subsequent paper.

In order to separate the different elements involved in the influence of moderate or severe cold on the tissue so that the study of the direct effect of cold could be carried on the authors selected the free split-thickness dermatome skin graft. Free skin grafts are peculiarly suitable for such a study (a) they are uniform in thickness (b) they are deprived of nerve and blood supply (c) they can be subjected to various measured temperatures for definite periods of time and (d) they can be replaced on a suitable bed in the host where their behaviour can be studied by biopsies and other methods.

The range of temperature extended from 39° to -108° F (4° to -78° C) and the time of exposure varied from a few hours to several months. The details of this method will be described in subsequent reports.

Observations were carried out on the vascular response of normal intact skin to the influence of a whole range of cold temperatures. This was

compared with the reaction of (a) recently healed donor sites where the restitution of the nervous system had not yet taken place (b) pedicle flaps deprived of their nervous connection with the body and (c) the recently healed and old skin grafts. Thus the authors were able to interpolate the role of nervous elements in the summation of reactions to cold and freezing.

In actual clinical cases other factors must be considered which may play a contributory and even a determining part in the final outcome of the injury by cold. These include the state of peripheral circulation in the individual the presence of specific vascular disease the individual susceptibility to cold the condition of the skin of the exposed part the local factors which prevail at the time of exposure (e.g. wetness constriction immobilization) and many others. Some of these factors have been appraised by studying the effect of reduced temperatures on healed scars donor sites skin grafts and tube pedicles under conditions in which the temperature as well as the duration of the exposure was known.

Thus it is possible to correlate the information obtained from the experimental studies with the clinical problems in which the condition of exposure to cold is unknown and the extent of tissue damage and prognosis are not immediately determinable.

LOUIS T. BYARS, M.D.

Control of Hemorrhage from Wounds of the Heart by the Gelatin Sponge Patch Technique.
HILGER PEARY JENKINS, HOWARD OWEN EDWARD SENT, and ROBERT W. JAMPOLIN. *Ann. Surg.*, 1947
126 973

The use of the gelatin sponge for hemostasis has previously been reported in cases of bleeding from wounds of the liver kidneys spleen vena cava and aorta.

In this experiment on dogs, a wound was made in the right or left ventricle with a scalpel to permit a large profuse spurt of blood with each systole. A sheet of dry compressed gelatin sponge was applied over the spurting wound and held in place by the operator's fingers with moderate pressure synchronized with the contractions of the heart while traction was made on a suture passed through the apex. Pressure was maintained over the patch for from 3 to 5 minutes for wounds of the right ventricle and from 5 to 13 minutes for wounds of the left ventricle. After this period of time the patch was usually sufficiently adherent to control the hemorrhage completely. After from 20 to 30 minutes the patch was usually firmly adherent to the heart and some times difficult to remove because of its fibrous fixation to the wound. The pericardium was sutured and the wound in the chest closed.

It was rather an important point in the technique to maintain even pressure on the patch so that when the blood clotted in the sponge, the patch would become adherent about the wound as a result of the liberation of fibrin during the clotting process. The

dry compressed sponge would stick to the gloved fingers very easily. Moistening the gloves with saline solution just before applying the patch would usually suffice to prevent this. A piece of perforated silkoid over the patch will prevent the sponge from sticking to the gloves. The silkoid should always be removed.

In a series of 15 experiments, the wound was made in the right ventricle in 4 cases and in the left ventricle in 11. The hemorrhage was completely controlled by the application of a gelatin sponge "patch" and the animal survived the immediate postoperative period. Six other animals died from ventricular fibrillation when the pericardial sac was opened or when the wound was made in the heart. The most satisfactory means of preventing fibrillation appeared to be careful handling of the heart and especially avoiding torsion.

In the series of 15 animals 5 died between 1 and 12 days from distemper pneumonia, or empyema. One died after 3 days from pneumonia but also had an intracardiac thrombosis due to the migration of the sponge patch into the cardiac chamber. In 2 of the animals there was a grayish appearance of the pericardial sac suggestive of an early pericarditis although no exudate was present.

There was no evidence of blood in the pericardial sac. The closure of the pericardium appeared to be a adequate additional support to the sponge to prevent subsequent blowing off of the "patch."

The gelatin sponge "patch" was firmly adherent to the heart, and usually only lightly adherent to the overlying pericardium. As a rule, the sponge appeared to undergo absorption in about 2 months. After several weeks the wound was healed by a well differentiated fibrous tissue scar.

Aside from the hemostatic effect of the sponge, it should also be pointed out that the sponge "patch" provides protective cover to the wound and gives it support during the process of wound repair.

The gelatin sponge may provide a means of obtaining immediate control of hemorrhage from a wound of the heart and at least momentarily preventing further loss of blood. It is thoroughly possible that with the hemorrhage controlled in this fashion, one could then very gently peel back the sponge and insert the suture in a relatively dry field or the suture could be placed in the wound and tied over the patch of sponge covering the wound. In wounds adjacent to the coronary vessels the gelatin sponge patch alone may suffice.

PORTACAVAL SHUNTS IN THE TREATMENT OF PORTAL HYPERTENSION

An Analysis of 15 Cases with Special Reference to the Suture Type of
End-to-Side Splenorenal Anastomosis with Splenectomy and
Preservation of the Kidney

ROBERT R. LINTON M.D. F.A.C.S., IRAL B. HARDY, Jr. M.D. and
WADE VOLWILER M.D., Boston, Massachusetts

PORTAL hypertension develops secondary to partial or complete obstruction of the portal blood flow in human patients. The site of the block may be either in the liver the intrahepatic type or in the portal venous system, the extrahepatic type, as has been pointed out by Whipple (20). Esophageal varices develop as a result of either type of block. These vessels are one of the main collateral channels through which nature shunts the blood flow around the site of obstruction from the portal bed to the systemic venous system. This shunt is obviously ineffective for two reasons. First, the fact that portal hypertension persists indicates the inadequacy of it in shunting the large volume of portal blood flow and, second, severe hemorrhage from rupture of the esophageal varices often occurs and may eventually cause death. Since the demonstration in 1877 by Eck that it is possible to anastomose the portal vein to the inferior vena cava in experimental

animals a number of surgeons in the past have attempted shunt operations in patients with portal hypertension (7, 9, 13, 16) according to Whipple (20). These attempts at direct venous anastomoses were rarely successful undoubtedly due to technical difficulties so that for several decades the indirect type of anastomosis the Talma Morrison (14, 18) operation or omentopexy was frequently performed. An occasional patient was benefited temporarily especially if splenectomy was also done. The majority, however, were not improved so the operation practically has been abandoned.

The recent perfection by Blakemore and Lord (3) of blood vessel anastomoses by the nonsuture technique utilizing vitallium tubes has restimulated surgeons in attacking the problem of portal hypertension. Whipple (20) and Blakemore and Lord (4) were the first to report a group of patients in which this method of venous anastomosis was utilized to produce portacaval shunts. They described two types of shunt (1) an end-to-end anastomosis between the splenic vein and left renal vein with splenectomy and nephrectomy and (2) an end-to-side anastomosis between the end

From the Departments of Surgery and Medicine, Massachusetts General Hospital.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, New York, September 8 to 11, 1947.

of the portal vein and the side of the inferior vena cava. The results in their cases have been so encouraging that it has stimulated us to a renewed attack on the problem.

The purpose of this paper is to discuss various types of portal bed block and to report a group of 15 cases in which patients have been treated by various types of shunt operations with particular reference to the suture type of end-to-side splenorenal anastomosis with splenectomy and preservation of the left kidney.

TYPES OF PORTAL BED BLOCK

Portal bed block may be one of two types, intrahepatic or extrahepatic as pointed out by Whipple (20) or a combination of both.

TABLE 1—TYPES AND ETIOLOGY OF PORTAL BED BLOCK MASSACHUSETTS GENERAL HOSPITAL

- I. Intrahepatic—
 - A. Portal cirrhosis (Laennec type) with or without cavernomatous transformation of the portal vein.
 - B. Thrombosis of hepatic veins.
- II. Extrahepatic (Banti's syndrome)—
 - A. Congenital—obliteration of the portal vein with cavernomatous transformation.
 - B. Acquired—thrombosis of the portal vein or its tributaries
 - 1. Infectious
 - 2. Traumatic
 - 3. Spontaneous
- III. Combined type—
 - Portal cirrhosis with portal vein thrombosis.

The relative frequency of the two types has not been determined because of the lack of statistical data. The most common form of intrahepatic block results from portal or Laennec's cirrhosis secondary to the scar tissue replacement of the liver parenchyma. The block is distal apparently to the hepatic veins since Herrick showed that in the normal liver perfusion of the hepatic artery alone with a manometer connected with the portal vein produced a 1 millimeter rise of mercury in the latter for every 40 millimeters rise in the former while in the cirrhotic liver there was a 1 millimeter rise in the portal vein for every 6 millimeters in the hepatic artery. These observations indicate that a considerable volume of the hepatic artery blood flow is blocked from entering the hepatic veins and is shunted back

into the portal vein thus increasing the blood flow through the collateral channels. It seems possible under these conditions that a type of an arteriovenous fistula is produced in the liver which if true would tend to increase the volume flow of blood in the portal system. Six patients in the report had a portal bed block of this type. The other type of intrahepatic block is secondary to thrombosis of the hepatic veins. This condition is relatively uncommon but when it occurs is usually fatal.

The extrahepatic portal bed block (so called Banti's syndrome) may be either congenital or acquired. The liver is normal early in the course of this type of disease but in the later stages may develop cirrhosis. The block in the former occurs in the portal vein and is usually due to fibrous or scar tissue. Whipple (20) has pointed out that it occurs probably from an extension into the portal vein of the process which obliterates the umbilical vein and the ductus venosus following birth. This explanation appears plausible since this type of the disease may occur early in life. Severe hematemesis occurred in 2 of our patients at the ages of 6 and 7 years, respectively. These children had had no serious illnesses or injuries since birth that might have caused the acquired form of portal block. Four other cases in this group of patients can be added to these since the disease manifested itself before 20 years of age.

The acquired type is thought to develop secondary to a thrombosis of the portal vein or one of its main tributaries, especially the splenic vein as pointed out by Warthin in 1910. The etiology of the thrombosis may be either infectious, traumatic, or spontaneous in origin. As in venous thrombosis elsewhere there may be partial canalization of the involved vessels and possibly portions of the thrombus may break off to produce portal emboli, thereby increasing the degree of portal bed block. Eight patients in this report had the extrahepatic type of portal bed block, 6 were classified in the congenital group and 2 in the acquired.

A combination of the two main types, the intrahepatic and extrahepatic, It
 1 in 2 of the patients
 cases 2 and 3. Whipple
 d in de

scribes another form of extrahepatic block, the so called cavernomatous transformation of the portal vein. Some authorities believe this may represent a vascular neoplastic lesion, an angioma in the hepatoduodenal ligament. It is our opinion however that the myriad of small blood vessels encountered in this region in many of the patients probably represents collateral channels that have developed as a result of the block in the portal system. Attempts to perform a direct anastomosis between the portal vein and the inferior vena cava had to be abandoned in several patients both with and without cirrhosis because of the extreme vascularity of this area. Similar vessels have been encountered frequently in the splenic and retroperitoneal regions during the performing of the splenorenal type of shunt. It would appear therefore that this type of vascular lesion in the region of the portal vein itself does not represent a specific form of extrahepatic block but may develop as a result of portal vein obstruction whatever the cause. Why it occurs in some cases and not in others is difficult to explain unless it is the degree of block and the duration of it.

DIAGNOSIS

Patients with portal hypertension secondary to a portal bed block, as a rule seek medical advice because of a sudden massive hematemesis. Melena in a few instances although far less frequently may be the first symptom since bleeding may occur elsewhere in the gastrointestinal tract especially in the stomach where large dilated veins are frequently encountered. Portal hypertension therefore should always be considered in the differential diagnosis of hematemesis or melena. There are few if any specific premonitory symptoms of the disease. Physical examination as a rule reveals an enlarged spleen, the so-called congestive splenomegaly. Blood examinations show a secondary anemia, a leucopenia and a thrombocytopenia. If the block is intrahepatic, the liver may or may not be enlarged whereas in the extrahepatic type it is usually normal in size. Further differentiation between the two types is determined by liver function tests. As a rule when the block is intrahepatic, there is a high retention of brom

Fig. 1. A roentgenogram of the esophagus, showing dilated esophageal varices. This is the most definite method of diagnosis of portal hypertension.

sulfalein, a reversal of the albumin globulin ratio, a positive cephalin flocculation test and an elevated prothrombin time whereas normal liver function tests indicate an extrahepatic block.

Röntgenologic examination of the esophagus with barium to determine the presence or absence of varices especially at the lower end of this organ is the most important diagnostic procedure in patients suspected of having portal hypertension. The method has been described fully by Schatzki (17) (Fig. 1). At the present time it is our belief that the presence of esophageal varices indicates portal hypertension secondary to either an intrahepatic or extrahepatic portal bed block.

CASE REPORTS—INTRAHEPATIC GROUP

CASE 1. M. L. V. No. 161,562, a 30 year old white housewife was first admitted to the Massachusetts General Hospital on November 8, 1938 because of increased vaginal bleeding of several months

duration. A gastrointestinal series showed no esophageal varices. The patient was discharged on November 10, 1938. Second admission December 12 to December 23, 1938 was because of vaginal bleeding. Treatment consisted of dilatation of cervix and curettage of uterus. Third admission May 26 to June 16, 1939 again for vaginal bleeding. Treatment consisted of supravaginal hysterectomy. A biopsy of the liver revealed alcoholic cirrhosis. Fourth admission May 10 to May 29, 1943 was for the excision of a mixed tumor of the right parotid gland. Fifth admission December 23, 1944 to January 24, 1945 was because of a small hematemesis of 1 day's duration. The liver and spleen were readily palpable. Laboratory studies revealed red blood cells, 3.4 million hemoglobin 7.4 grams white blood cells, 11,000 prothrombin time, 28 seconds with a normal of 20 seconds. The total serum protein was 6.4 grams with an albumin-globulin ratio of 3.0. The cephalin flocculation was 4+ in 48 hours and the bromosulfalein retention was 15 per cent in 45 minutes. A gastrointestinal series revealed large esophageal varices. She was discharged home to report in 1 month to have a portacaval shunt performed. Sixth admission February 21 to March 24, 1945 was for operation, which was performed March 6, 1945. A splenectomy, left nephrectomy and an end-to-end splenorenal anastomosis was performed by Richard H. Sweet, who used the nonsuture method with a Blakemore vitallium tube. A liver biopsy showed moderate cirrhosis with some hepatic regeneration. The patient was last seen on August 8, 1947. She had had no episodes of bleeding, except a few streaks of red blood on her stools which were attributable to hemorrhoids. Red blood cells numbered 4.0 million hemoglobin 12.9 grams. A gastrointestinal series revealed no change in the esophageal varices.

This patient it is believed, is an example of intrahepatic portal bed block secondary to portal cirrhosis of the liver. She had had only one minor hematemesis prior to admission and none since the shunt was performed. Liver function tests repeated about 2 years after the operation showed slight improvement. Esophagoscopy performed 24 months after the operation by Edward B. Benedict, revealed the presence of a few varices which were injected with a sclerosing solution. The operative procedure consisted of a splenectomy, left nephrectomy and a Blakemore nonsuture type of end-to-end splenorenal anastomosis, the only one of this type in this report. The result to date is gratifying and gives us our longest follow up. At observation 29 months after shunt operation she had had no further bleeding which is encouraging although an esophagogram still showed esophageal varices.

CASE 2 C. P. No. 323 585 a 42 year old white male electrician was first admitted to the Medical Service of the Massachusetts General Hospital on June 13, 1942 because of repeated episodes of hematemesis and tarry stools of 5½ months' duration. During this time he had been admitted to outside hospitals on three occasions and received many transfusions. He admitted moderate alcoholic intake. Examination revealed a middle-aged man with a prominent abdomen and an enlarged liver and spleen. Laboratory studies revealed red blood cells, 4.8 million hemoglobin, 10.5 grams white blood cells, 7,500 total serum protein 6.2 grams albumin-globulin ratio, 1:1 nonprotein nitrogen, 32 milligrams, van den Bergh normal, cephalin flocculation, 3+ in 48 hours prothrombin time 30 seconds with a normal of 21 seconds. A gastrointestinal series showed extensive varices of the esophagus and stomach. The patient was discharged on June 22, 1942. Second admission December 24 to December 31, 1942 was because of hematemesis. Third admission, February 2, 1943 to April 7, 1943 was because of further esophagogastrintestinal bleeding. On March 1, 1943 a splenectomy was performed through a transthoracic exposure by Richard H. Sweet. Fourth admission, July 20 to July 24, 1943 was because of recurrent hematemesis. Fifth admission October 31 to December 23, 1943 was because of hematemesis of 4 days duration. Treatment was complicated by transfusion reactions and also a posterior myocardial infarction. Sixth admission, January 27 to February 3, 1944, was because of hematemesis. Seventh admission August 28 to August 31, 1944, was because of melena. Eighth admission April 5 to April 14, 1945, was because of hematemesis. Treatment consisted of a transfusion. Ninth admission, May 22 to June 8, 1945 was for severe generalized abdominal pain with a white blood cell count of 38,000. Treatment was conservative. Tenth admission August 20 to September 1, 1945, was because of hematemesis. Treatment consisted of esophagoscopy and injection of esophageal varices with 5 per cent sodium morrhuate solution. Eleventh admission, October 11 to October 23, 1945 was because of deep venous thrombosis of the left leg. Treatment consisted of bilateral superficial femoral vein interruption. Twelfth admission, November 13 to November 28, 1945, was to perform a portacaval shunt. Red blood cells numbered 4.5 million hemoglobin 9.4 grams nonprotein nitrogen, 16 milligrams per cent, total serum protein 6.64 grams and albumin-globulin ratio 1:77 prothrombin time 23 seconds with a normal of 18 seconds cephalin flocculation was 3+ in 48 hours. Operation was performed November 1, 1945. A suture anastomosis was made between the proximal end of the divided superior mesenteric vein and the side of the inferior vena cava by one of us (R. R. L.). The patient developed oliguria postoperatively for 48 hours and then his output increased but his nonprotein nitrogen rose steadily being 74, 116 and 154 milligrams per cent on the second, third and fifth postoperative days. He had a terminal hemorrhage

by mouth and died on November 28 1945 one week following the operation. Autopsy revealed cirrhosis of the liver hemoglobin nephrosis and some pulmonary congestion and edema. The venous anastomosis was patent. There was evidence of old portal vein thrombosis with canalization.

This patient it is believed, is an example primarily of intrahepatic portal bed block secondary to portal cirrhosis but in addition complicated by portal vein thrombosis as proved at autopsy. Splenectomy in 1943 failed to relieve the portal hypertension, since repeated esophagogastrintestinal hemorrhages continued to occur the first one within 4 months of the splenectomy. It was decided that a portacaval shunt should be performed, although it was realized that his general condition and cardiac status were poor. The spleen having been previously removed precluded a splenorenal anastomosis and because of marked vascularity in the region of the portal vein a superior mesenteric vein to inferior vena cava anastomosis was performed in November 1945. The patient died from renal failure 1 week after the operation. It is believed in retrospect that a splenorenal anastomosis should have been done at the time the spleen was removed but unfortunately this operation was not in vogue at that time. The shunt operation was undertaken finally as a last resort 2 years later in a patient doomed to die from hemorrhage and whose general condition had deteriorated considerably during this period.

CASE 3 A. C. No 416 195 a 54 year old white porter was first admitted to the Massachusetts General Hospital on January 15 1945 because of massive and abdominal swelling of 3 weeks duration and one episode of hematemesis. Examination revealed a middle aged man with a distended abdomen with an enlarged liver and spleen and ascites. Laboratory studies revealed red blood cells 3.69 million hemoglobin 13 grams white blood cells 3,000 nonprotein nitrogen 23 milligrams per cent total serum protein 7.05 grams albumin globulin ratio 0.8 cephalin flocculation 4+ in 48 hours prothrombin time, 20 seconds with a normal of 18 to 20 seconds bromsulphalein retention test showed 40 per cent retention. A gastrointestinal series was negative except for large esophageal varices. The patient was treated conservatively and was discharged improved on February 2 1945. Second admission December 29 1945 to January 31 1946 massive ascites and scrotal edema. The patient received blood transfusions and repeated abdominal paracenteses. The total serum protein was 5.04 grams albumin-globulin

ratio 0.98 cephalin flocculation was 4+ in 48 hours and bromsulphalein retention was 20 per cent in 45 minutes prothrombin time 38 seconds with a normal of 20 seconds but it improved to 25 seconds with a normal of 20 seconds. At operation January 28 1946 a suture anastomosis between the end of the portal vein and the side of the inferior vena cava distal to the renal veins was made by one of us (R. R. L.). A large partially organized thrombus was removed from the portal vein after the vein was divided. The patient became comatose on the second postoperative day and died on the third postoperative day. Autopsy revealed portal cirrhosis of the liver and a patent anastomosis between the portal vein and the inferior vena cava. The cause of death was thrombosis of the hepatic artery.

This patient it is believed is an example of intrahepatic portal bed block with a superimposed extrahepatic block from portal vein thrombosis. Despite marked vascularity in the gastrohepatic ligament consistent with the so called cavernomatous transformation of the portal vein a satisfactory portacaval anastomosis was performed. The patient however died on the third day after the operation due to thrombosis of the hepatic artery presumably from operative trauma. In retrospect it is believed that a splenectomy and a splenorenal type of anastomosis would have been the preferable operation because of the extreme vascularity in the region of the portal vein.

CASE 4 M. F. F. No 528,413 a 42 year old white male cab driver was first admitted to the Massachusetts General Hospital on April 7 1946 because of severe repeated hematemesis of 5 days duration. During the year before admission he had been hospitalized on 4 occasions because of hematemesis. Examination revealed a poorly nourished man with many spider telangiectases. The liver and spleen were both palpable. Laboratory studies revealed red blood cells 2.0 million hemoglobin 8 grams white blood cells 5,800 total serum protein 5.7 grams with an albumin globulin ratio of 1.09 the nonprotein nitrogen was 26 milligrams per cent the cephalin flocculation 3+ in 48 hours the prothrombin time was 28 seconds with a normal of 22 seconds serum bilirubin 1.6 milligrams per cent bromsulphalein was 36 per cent retention in 45 minutes. A gastrointestinal series revealed large esophageal varices. Before discharge on June 12 1946 he was esophagoscopied and some varices were injected with a 5 per cent solution of sodium morrhuate. Second admission July 19 to August 19 1946 was because of massive hematemesis. The patient was prepared for operation and a portacaval shunt was planned. At operation August 19 1947 the abdomen was opened through a long right subcostal incision by one of us (R. R. L.). Because of the extreme vascularity in

the region of the portal vein, it was impossible to isolate this blood vessel. Extensive bleeding was partially controlled with fibrin foam. The patient received 3,500 cubic centimeters of citrated blood and 5,000 cubic centimeters of blood by autotransfusion. He left the operating room in poor condition and never regained consciousness. He died about 5 hours following the operation. An autopsy revealed massive intra abdominal hemorrhage.

This patient it is believed is an example of intrahepatic portal bed block secondary to portal cirrhosis with a superimposed cavernomatous transformation of the portal vein. During the operation in which a portacaval anastomosis was attempted but had to be discontinued because of severe hemorrhage before the portal vein was isolated the patient received 17 citrated blood transfusions a total of 8,500 cubic centimeters of blood. The fact that his death resulted from hemorrhage would seem to indicate that patients with severely damaged livers apparently do not metabolize the citrate used as the anticoagulant in the transfusions. This patient received 2,125 cubic centimeters of a 13 per cent citrate solution. This amount in patients with normal livers has not produced incoagulability of the blood. In retrospect it is believed that it would have been better in this patient to have performed a splenectomy and a splenorenal anastomosis, or at least the operation should have been terminated when the extreme vascularity of the subhepatic region was recognized.

CASE 5 E. E. B. No. 505,360 a 51 year old white business man was admitted to the Phillips House of the Massachusetts General Hospital on September 4, 1935 because of weakness, apathy, and increase in abdominal girth of several months' duration. He gave a long history of large daily alcoholic intake. Examination revealed a slightly emaciated and icteric middle aged man with a fluid wave in the abdomen. His liver was enlarged the spleen could not be palpated. Laboratory studies revealed red blood cells 3.71 million white blood cells 8,700 serum protein was 5.2 grams albumin-globulin ratio 1:1.3 nonprotein nitrogen 8 milligrams per cent prothrombin time 3 seconds with a normal of 16 seconds serum bilirubin 2.16 milligrams per cent bromsulphalein test was 38 per cent in 45 minutes. A gastrointestinal series revealed large esophageal varices and liver biopsy showed extensive cirrhosis of the alcoholic type. With conservative measures he improved and was discharged on November 21, 1935. Second admission, June 2, 1936 for study. Third

admission, August 8, 1946 was because of hematemesis and for abdominal paracentesis. Fourth admission August 30 to September 1, 1946 was for paracentesis. Fifth admission September 12 to September 7, 1946 was for abdominal paracentesis. Sixth admission November 17 to December 12, 1946, was because of massive hematemesis. During this admission the patient continued to have repeated massive hematemesis. The patient was rapidly losing ground so an exploration was decided upon in the hope of accomplishing some form of portacaval shunt. At operation, December 10, 1946 a splenectomy with an end-to-side suture splenorenal anastomosis was done by one of us (R. R. L.). Following the operation the patient failed to recover consciousness. He developed pulmonary edema and oliguria and died December 12, 1946 48 hours after the operation. Autopsy examination revealed extensive cirrhosis with massive hemorrhages from the varices. The anastomosis was patent.

This patient, it is believed is an example of intrahepatic portal bed block secondary to portal cirrhosis treated by splenectomy and splenorenal anastomosis. Injection of the esophageal varices with a sclerosing solution before operation did not control the bleeding from them. During the 5 days before operation, he vomited repeatedly large amounts of blood so that a splenectomy and a splenorenal anastomosis were performed as a last resort and as an emergency procedure. In retrospect it is believed that this type of patient was too critically ill to attempt such a formidable operative procedure. Perhaps earlier in the course of his disease before he had become so depleted it might have been successfully performed.

CASE 6 B. P. M. No. 561,984, a 54 year old white male restaurant owner was first admitted to The Baker Memorial Hospital on January 26, 1947 because of chills, fever and jaundice of 8 days' duration. He had been a heavy drinker. Physical examination showed a jaundiced middle-aged man with ascites. Laboratory studies revealed red blood cells 3.5 million hemoglobin 11 grams white blood cells 8,500 nonprotein nitrogen 21 milligrams per cent total serum protein, 8.16 grams with an albumin globulin ratio of 0.77 cephalin flocculation was 4+ in 48 hours prothrombin time was 27 seconds with a normal of 18 seconds van den Bergh was 4.2 milligrams per cent bromsulphalein test was 40 per cent retention in 45 minutes. A gastrointestinal series was suggestive of esophageal varices. Repeated paracenteses were performed because of rapid accumulation of abdominal fluid. A liver aspiration biopsy done by Wade Volwiler on February 6, 1947 showed a marked degree of cirrhosis with extensive

dilatation of the venous sinusoids and narrowing of the liver cord cells. Despite this poor liver function it was felt that his disease was fatal unless a portacaval shunt could be performed. At operation April 7, 1947, a splenectomy and an end-to-side suture splenorenal anastomosis were done by one of us (R. R. L.). The operative field was very vascular. It was necessary to give the patient many transfusions and after 15–6 of them bank blood and 9 auto-transfusions it was noted that the patient was bleeding more profusely and the blood would not clot. In spite of 6 grams of intravenous calcium and vitamin K the bleeding continued. The operative incision was closed around the suction tip through which the blood was aspirated and given back to the patient. In all he received by vein a total of approximately 27,000 cubic centimeters of blood. All but 3,000 cubic centimeters of this was by autotransfusion. He rapidly failed and died 2 hours after the operation. Autopsy was not permitted.

This patient it is believed is an example of intrahepatic portal bed block secondary to portal cirrhosis of the liver, with a superimposed thrombosis of the hepatic veins. This latter diagnosis was suggested by Chester M. Jones because ascites developed suddenly and reaccumulated extremely rapidly and an aspiration biopsy of the liver showed extensive dilatation of the venous sinusoids. Operation was undertaken in this patient as a last resort. In retrospect it is believed that he was a patient with a liver too severely damaged to withstand such a long extensive surgical procedure. His case demonstrates also the inability of a badly damaged liver to metabolize the citrate used in multiple blood transfusions.

CASE 7. C. D. No. 577,750, a 51-year-old white man was admitted to the Massachusetts General Hospital on June 9, 1947, because of recurrent episodes of hematemesis of 8 months' duration. In April 1947 a diagnosis of bleeding duodenal ulcer was made at another hospital. As a result an exploratory laparotomy was performed at which time a diagnosis of cirrhosis with portal hypertension was made. Hematemesis developed 7 days after the operation, and he was transferred to the Massachusetts General Hospital. Physical examination revealed a pale, scrawny man. The liver and spleen could not be palpated. Laboratory studies revealed hemoglobin 8 grams, white blood cells 3,500, prothrombin time 20 seconds with a normal of 15 seconds, nonprotein nitrogen 27 milligrams per cent, total serum protein 7.49 grams, albumin-globulin ratio 1:7, cephalin flocculation test was 3+ in 48 hours, the van den Bergh was normal, the bromsulphalein test 12 per cent retention in 45 minutes. Roentgenogram of the esophagus showed extensive esophageal varices. A

diagnosis of portal cirrhosis with a relatively good liver function was made and a portacaval shunt recommended. On June 23, 1947, a splenectomy and an end-to-side suture splenorenal anastomosis were made by one of us (R. R. L.). The patient made an uneventful convalescence and was discharged on July 6, 1947, 13 days following the operation. A check up 2 months after the operation revealed that the patient was in excellent condition and had no further significant gastrointestinal bleeding.

The patient it is believed is an example of intrahepatic portal bed block secondary to cirrhosis of the liver. The liver function test showed light to moderate disease. Attention should be drawn to the fact that the diagnosis of cirrhosis with esophageal varices was missed in hospital because the roentgenologists failed to visualize the esophagus carefully. As a result the patient was put through an unnecessary laparotomy before the diagnosis was made. The result to date is encouraging but further observation is necessary.

CASE REPORTS—INTRAHEPATIC GROUP

CASE 1. M. N. No. 21,099, a 12-year-old white boy was first admitted to the Massachusetts General Hospital on December 1, 1929, because of hematemesis. He had been admitted to the Children's Hospital in 1925 and 1927 because of similar episodes. In that institution he had been transfused and his bleeding stopped spontaneously. After his admission to the Massachusetts General Hospital a splenectomy was performed through an abdominal approach by Arthur W. Allen. The patient did well and was discharged on January 25, 1930. Second admission November 11 to December 24, 1930, was because of repeated hematemesis. On December 12, 1930, re-exploration of the abdomen by Allen and the dilated veins in the gastrohepatic omentum were ligated. Third admission January 15 to January 27, 1931, was for a tonsillectomy. Fourth admission April 23 to May 16, 1932, was for hematemesis. Fifth admission February 14 to February 25, 1937, was because of hematemesis although he had been well for a period of 5 years. Sixth admission December 15 to December 16, 1944, was because of hematemesis. Treatment consisted of esophagoscopy with injection of varices with 5 per cent solution of sodium morrhuate. Seventh admission January 8 to January 9, 1945, was for esophagoscopy with injection of esophageal varices. Eighth admission February 24 to March 14, 1945, was for relief of hematemesis. Multiple transfusions were administered. Ninth admission April 9 to April 10, 1945, tenth admission May 14 to May 15, 1945, eleventh admission July 13 to July 14, 1945, were for esophagoscopy and injection of esophageal varices. Twelfth admission September 27 to October

4 1945, was because of massive hematemesis. Laboratory studies revealed red blood cells, 4.4 million hemoglobin 85 per cent white blood cells 9,300 prothrombin time, 19 seconds with a normal of 16 seconds. At operation October 9, 1945 an end-to-side suture anastomosis between the proximal divided end of the superior mesenteric vein and the side of the inferior vena cava was performed by one of us (R. R. L.) The patient was discharged home 13 days following the operation. Follow-up. He was seen on August 8 1947 22 months following the operation. He had had no bleeding and was working full time as a painter. A gastrointestinal series revealed no change in the esophageal varices.

This patient it is believed, is an example of extrahepatic portal bed block of congenital origin secondary to obliteration of the portal vein. He was treated by a superior mesenteric to inferior vena cava shunt. Surgical therapy including splenectomy transabdominal ligation of veins in the gastrohepatic ligament numerous injections of esophageal varices with sclerosing solutions, was ineffective in controlling hemorrhage from esophageal varices. These procedures had not controlled the portal hypertension since the portal pressure was found to be 47 centimeters of saline at the operation in 1945 a little more than four times the normal. The fact that 22 months have elapsed since his portacaval anastomosis without further bleeding is encouraging that this operation may have been successful in reducing the portal hypertension. His case is of especial interest since he appears to be one of the previously splenectomized patients that has been salvaged and in addition one of 2 patients apparently successfully treated by anastomosis between the superior mesenteric vein and the inferior vena cava. The other was by Bogart in 1913 according to Whipple (20).

CASE 9. R. M. No. 516,023 a female child, aged 6 years was first admitted to the Children's Medical Department of the Massachusetts General Hospital on January 6, 1946 with a complaint of fever and nose bleeds 4 days duration. Physical examination revealed a small, pale young girl. The liver was normal in size and the spleen enlarged. A gastrointestinal series revealed one large varix visible at the lower end of the esophagus. The findings were consistent with so-called Banti's syndrome. Laboratory studies revealed red blood cells, 3.5 million hemoglobin 9 grams white blood cells, 6,000 prothrombin time, cephalin flocculation, bromsulphalein and van den Bergh tests were normal serum protein, 6.34 grams albumin-globulin ratio 2:14 nonprotein

nitrogen 24 milligrams per cent. The patient's condition gradually improved and she was discharged on February 6 1946 with a diagnosis of pancytopenia. Second admission, April 27 to July 13 1946 was because of severe hematemesis. Laboratory studies revealed red blood cells 1.9 million hemoglobin, 4.4 grams white blood cells, 47,000 serum protein, 4.9 grams. The patient's diagnosis was reconsidered and it was decided in view of the hematemesis, the esophageal varices and the enlarged spleen that treatment should consist of a splenectomy and a splenorenal shunt. At operation June 4, 1946, a splenectomy and an end-to-side suture type of splenorenal anastomosis were performed by one of us (R. R. L.) The postoperative convalescence was complicated by a massive hemothorax and hemoperitoneum believed secondary to the administration of heparin for 7 days following the operative procedure. The patient, however, made a slow but satisfactory convalescence following this serious complication and she was discharged 39 days after the operation. Follow-up. The patient returned to school in October 1946. She was seen on August 8 1947 was leading a normal, active existence without further hematemesis. Blood studies revealed hemoglobin, 13.5 grams red blood cells, 4.25 million, white blood cells, 7,000. A repeat roentgenogram of the esophagus showed no change in the esophageal varices.

This patient it is believed is an example of extrahepatic portal bed block of congenital origin secondary to obliteration of the portal vein, treated by a splenectomy and an end-to-side splenorenal shunt. Measurements of portal pressure indicated that the shunt was functioning since the initial level at the time of the operation was 49 centimeters of saline and following the splenectomy and splenorenal anastomosis it had dropped to 21.5 centimeters of saline. The well being of the patient and the absence of further hemorrhages from the gastrointestinal tract for a period of 14 months since the operation was performed are encouraging and indirect evidence that the portal hypertension has been reduced.

CASE 10. J. M. No. 36 a 19 year old white male dental mechanic, was first admitted to the East Medical Service of the Massachusetts General Hospital on November 6 1935 because of melena associated with epigastric distress. The liver and spleen were both palpable. A gastrointestinal series revealed extensive esophageal varices. A diagnosis of Banti's disease was made. On December 5 1935 the splenic artery was ligated in continuity by Beth Vincent and an extensive omentopexy was performed. The patient was discharged December 20, 1935. Second admission, January 2 to March 2, 1937 was because of hematemesis and melena. He had repeated massive

hematemesis while in the hospital. A second operation by Arthur W. Allen was performed. Several large veins on the diaphragm and along the lesser curvature of the stomach were ligated and a further omentopexy was performed. Third admission: February 14 to March 17, 1939 for melena. Fourth admission: April 28 to May 16, 1939. Fifth admission: August 21 to September 5, 1939. Sixth admission: February 7 to March 2, 1940. Seventh admission: August 16 to September 20, 1940. Eighth admission: October 31 to November 6, 1940. Ninth admission: November 7 to December 23, 1940. Tenth admission: January 9 to February 6, 1941. Eleventh admission: February 13 to March 13, 1941. Twelfth admission: April 14 to May 2, 1941. Thirteenth admission: May 19 to May 21, 1941. Fourteenth admission: June 27 to June 28, 1941. Fifteenth admission: July 7 to July 8, 1941. Sixteenth admission: July 9 to July 16, 1941. Seventeenth admission: August 6 to August 7, 1941. Eighteenth admission: September 19 to September 20, 1941. Nineteenth admission: November 14 to November 15, 1941. All for esophagoscopies and injection of esophageal varices. Twentieth admission: February 5 to February 6, 1942. Twenty-first admission: June 17 to June 26, 1942. Twenty-second admission: July 25 to August 12, 1942. Twenty-third admission: September 11 to September 12, 1942. Twenty-fourth admission: November 5 to November 14, 1942. Twenty-fifth admission: April 4 to May 13, 1943. Twenty-sixth admission: June 14 to June 15, 1943. Twenty-seventh admission: March 17 to March 18, 1944. Twenty-eighth admission: October 27 to October 28, 1944. Twenty-ninth admission: March 3 to March 4, 1945. Thirtieth admission: September 9 to September 10, 1945. All for esophagoscopies and injection of esophageal varices. Thirty-first admission: March 28 to March 30, 1946. Thirty-second admission: April 6 to May 29, 1946. All for esophagoscopies and injection of esophageal varices. Physical examination showed a markedly exsanguinated young man with an enlarged palpable spleen. Laboratory studies revealed red blood cells 3.0 million, hemoglobin 9.0 grams, serum protein 5.56 grams with an albumin-globulin ratio of 2.07, cephalin flocculation 3+ in 48 hours, van den Bergh normal, prothrombin time 23 seconds with a normal of 19 seconds, bromsulphalein test 6 per cent retention. It was decided in view of the past history of repeated esophagogastrintestinal hemor-

rhages that a portacaval anastomosis should be attempted. At operation April 24, 1946, exploratory laparotomy through a right abdominal incision was done by one of us (R. R. L.). The portal vein was searched for but it could not be found. Massive bleeding was encountered. The common duct was accidentally transected and the cystic duct was injured necessitating a cholecystectomy and a choledochojunostomy according to Allen's (1) method. A portacaval shunt could not be performed. The patient made a satisfactory convalescence. Thirty-third admission: June 6 to July 1, 1946. This was for a final attempt at a portacaval shunt. At operation June 8, 1946, a splenectomy and an end-to-side suture type of splenorenal anastomosis were performed by one of us (R. R. L.). Six thousand cubic centimeters of citrated blood were used. The operation required 6.5 hours. The convalescence was satisfactory. The patient was discharged 23 days following the operation. Follow up: When seen on August 8, 1947, 14 months after the operation, he felt well and had had no symptoms of bleeding. Hemoglobin was 17 gram, white blood cells 10,000. The esophageal varices appeared the same by x-ray.

This patient is believed to be an example of extrahepatic portal bed block of congenital origin secondary to obliteration of the portal vein. He was admitted to the hospital 33 times from 1935 to 1946. Eighteen of these admissions were for massive bleeding, 12 for melena and 6 for hematemesis. The other 15 were for esophagoscopies and injection of esophageal varices. His case demonstrates the inefficacy of controlling portal hypertension by ligation of the splenic artery, omentopexy, ligation of the left gastric and coronary veins, transthoracic ligation of the periesophageal veins, and repeated injections of the esophageal varices with a sclerosing solution. A splenectomy fortunately had not been accomplished so that the splenic vein was still available with which to do a splenorenal shunt. The utilization of a thoracoabdominal approach, multiple bank blood transfusions and autotransfusions, and preservation of the left kidney, it is believed, were of extreme importance in the successful outcome of the shunt operation in this patient. It is still too early, however, to consider the patient cured following the shunt operation but at least he has had 14 months without evidence of bleeding.

CASE 11: F. L., No. 333,628, a 16-year-old white school girl was first admitted to the West Medical Service of the Massachusetts General Hospital on December 25, 1941, because of hematemesis. The

spleen was palpable below the costal margin. A gastrointestinal series showed large esophageal varices. The laboratory studies including bromsulfalein retention test, cephalin flocculation, van den Bergh prothrombin time, bleeding clotting time were normal. A diagnosis of congestive splenomegaly with esophageal varices was made. On January 10, 1947, through a transthoracic approach, Richard H. Sweet performed a splenectomy and ligated several large periesophageal varices. Patient was discharged on February 28, 1947. Second admission April 1 to May 3, 1946, was because of hematemesis. She was discharged to return later for a shunt operation. Third admission July 5 to July 30, 1946. Liver function tests were normal. At operation July 3, 1946, exploratory laparotomy through a left subcostal incision was carried out by one of us (R. R. L.). The splenic vein was found to be too small for an end-to-side anastomosis. An inferior mesenteric to left ovarian vein shunt was performed. A liver biopsy showed normal liver. Initial portal pressure 35 centimeters of saline after the anastomosis 24 centimeters of saline. The convalescence was peaceful. Follow-up. The patient was seen 3 months after the operation and had had no further bleeding episodes from the esophagogastrintestinal tract. A gastrointestinal series in June 1947 revealed the varices to appear unchanged.

This patient it is believed is an example of extrahepatic portal bed block of congenital origin secondary to obliteration of the portal vein. Following a splenectomy and ligation of periesophageal veins she had no bleeding for 4 1/2 years. This case demonstrates that when the spleen has been removed at a previous operation the splenic vein no longer is usable for a splenorenal anastomosis. In this case it was necessary to anastomose the inferior mesenteric vein to the left ovarian vein. The fact that she has not bled for 13 months is encouraging. It would indicate that the shunt is still functioning. It is planned if further bleeding occurs to attempt a portal vein or superior mesenteric vein to inferior vena cava shunt.

CASE 12. F. B. No. 554,060, a 65 year old male dental supply worker was admitted to the Massachusetts General Hospital on October 24, 1946, because of massive hematemesis and melena. Physical examination revealed a man in shock with an enlarged liver and spleen. A gastrointestinal series revealed extensive lower esophageal varices. Laboratory studies after several transfusions revealed hemoglobin 9 grams, serum protein, 6 grams with an albumin-globulin ratio of 2, nonprotein nitrogen, 46 milligrams per cent, prothrombin time 16 seconds with a normal of 14 seconds, bromsulfalein test showed

34 per cent dye retention and a cephalin flocculation test was 1+ in 48 hours. Conservative treatment was instituted for the next 6 weeks and the liver function improved so that the bromsulfalein test showed only 6 per cent retention. At operation, January 11, 1947, a splenectomy and an end-to-side suture type of splenorenal anastomosis was performed by one of us (R. R. L.). The initial portal pressure was 23 centimeters of saline and following the completion of the anastomosis it was 14 centimeters of saline. A liver biopsy showed no definite evidence of underlying liver disease. The patient was discharged on February 1, 1947, 21 days following the operation. Follow-up. On August 8, 1947, he stated that he felt better than he had for several years, had gained 19 pounds, no further bleeding from the esophagogastrintestinal tract.

This patient it is believed is an example of acquired extrahepatic portal bed block secondary to thrombosis in the portal system, treated by splenectomy and an end-to-side splenorenal anastomosis. The liver function tests were normal except for a high retention bromsulfalein but a liver biopsy showed no underlying liver disease. The cause of the portal thrombosis is obscure so it must be classified as spontaneous. Further observation in this case will be necessary to determine the efficacy of the procedure.

CASE 13. M. M. C. No. 560,473, a 44 year old white woman was admitted to the East Medical Service on January 10, 1947, because of massive hematemesis. Physical examination revealed a pale woman, the liver was not palpable and the spleen could just be felt. Laboratory studies disclosed red blood cells 2.0 million, hemoglobin 7 grams, white blood cells, 2,700, a bromsulfalein retention test, prothrombin time, cephalin flocculation and albumin-globulin ratio were normal. A gastrointestinal series revealed esophageal varices. A diagnosis of portal hypertension with bleeding esophageal varices due to an extrahepatic portal bed block was made. At operation, February 7, 1947, a splenectomy and an end-to-side suture type of splenorenal anastomosis were performed by one of us (R. R. L.). The initial portal pressure was 34 centimeters of saline and following the anastomosis it was 24 centimeters of saline. She was discharged on February 24, 1947, 17 days after the operation. Follow-up. On August 8, 1947, she stated that she felt fine, had no abdominal pain, no further hematemesis or melena.

This patient it is believed is an example of acquired extrahepatic portal bed block secondary to thrombosis in the portal system. She was treated by splenectomy and end-to-side splenorenal anastomosis. The etiology of the portal thrombosis is obscure so that it must

be classified as spontaneous. The initial portal pressure was 34 centimeters and following the completion of the shunt it was 24 centimeters of saline. This observation in addition to the fact that she is well and has had no further bleeding episodes since the operation for a period of 6 months is encouraging that the shunt is still functioning but further observation will be necessary to evaluate the procedure.

CASE 14 M. M. No. 434,339, a 19 year old white woman, was first admitted to the West Medical Service of the Massachusetts General Hospital on February 4, 1944 because of repeated episodes of hematemesis over a 5 year period. The latest attack began 5 days before admission. The liver was not palpable. The spleen was three fingers below the costal margin. Laboratory studies disclosed red blood cells 4.0 million hemoglobin 15 grams white blood cells 6,400 total serum protein 7.38 grams with an albumin-globulin ratio of 1:3. A bromsulphalein test showed 40 per cent retention in 45 minutes cephalin flocculation showed 4+ in 48 hours the van den Bergh was normal. A gastrointestinal series showed esophageal varices. A liver biopsy revealed a normal liver. On March 9, 1944 through a transthoracic approach a splenectomy was performed by Richard H. Sweet and several large periesophageal vessels as well as the left gastric vessels were ligated. The patient was discharged April 3, 1944. Second admission December 12, 1944 to July 11, 1945 admission because of massive hematemesis. Hospitalization was greatly prolonged because of the onset of vague abdominal discomfort and persistent fever. Consensus was that the fever was due to thrombophlebitis in the portal system. At operation June 25, 1945 a portacaval anastomosis was attempted by one of us (R. R. L.) but was technically impossible because of a cavernomatous transformation of the portal vein. A liver biopsy was normal. Third admission December 11, 1946 to January 27, 1947 because of massive hematemesis. Liver function studies were normal. At operation, January 10, 1947 through a left abdominal incision the splenic vein was searched for by one of us (R. R. L.) but it could not be found nor was there any other vein suitable for a venous anastomosis. Fourth admission February 23 to February 28, 1947 was for hematemesis. Fifth admission March 4 to March 20, 1947 for another attempt at a venous anastomosis. At operation March 10, 1947 through a thoracoabdominal incision by one of us, (R. R. L.) an anastomosis between the inferior mesenteric vein and a large adrenal vein was accomplished. It was felt that decompression of the portal hypertension was not entirely satisfactory because of the small caliber of the operative anastomosis. Sixth admission July 25 to August 13, 1947 for hematemesis. Seventh admission August 15 to September 30, 1947 for hematemesis and another

and final attempt at a venous shunt. At operation September 10, 1947 another attempt at a direct portacaval anastomosis was made by one of us (R. R. L.) but again no vein including the portal vein could be found to make a satisfactory shunt.

This patient it is believed is an example of extrahepatic portal bed block of congenital origin secondary to obliteration of the portal vein. Her symptoms first appeared at the age of 14 years. She demonstrates the inefficacy of splenectomy with ligation of the left gastric and periesophageal veins in the control of portal hypertension. She also is an example of the difficulty of performing a satisfactory venous shunt operation when the spleen has been previously removed in this type of case due to a cavernomatous transformation of the portal vein which precludes using this vessel. In view of the experiences with this case it is our opinion that any surgeon who removes the spleen in a so-called case of Banti's syndrome should be prepared to perform a splenorenal shunt at the same operation since otherwise at a later time it will be impossible to find a satisfactory vein with which to perform a portacaval shunt.

CASE 15 J. S. No. 566,107, a 23 year old white single male factory worker was admitted to The Baker Memorial Hospital for the first time on February 28, 1947 because of repeated episodes of hematemesis. The patient had been well until 6 years before when he had had a sudden large hematemesis. On the day of admission to the Massachusetts General Hospital he was first seen by Chester M. Jones who immediately admitted him. Physical examination revealed a pale white young man. The liver and spleen could not be palpated. Laboratory studies hemoglobin 4.0 grams white blood cells 2,900 serum protein 6.5 grams with an albumin globulin ratio of 3:1 prothrombin time 17 seconds with a normal of 16 seconds cephalin flocculation 1+ in 48 hours bromsulphalein test 4 per cent retention a gastrointestinal series showed large esophageal varices. A diagnosis of portal hypertension with bleeding esophageal varices due to extrahepatic portal bed block (Banti's syndrome) was made. At operation March 13, 1947 a splenectomy and an end-to-side suture type of splenorenal anastomosis were performed by one of us (R. R. L.). The initial portal pressure was 42 centimeters of saline following the anastomosis it was 23 centimeters of saline. The patient made a good convalescence and was discharged from the hospital 2 weeks after operation. Follow up August 26, 1947. Patient reported that 5 months after operation he felt well was back at work weighed 158 pounds and had had no further evidence of esophagogastric intestinal bleeding.

Fig. An artist drawing to show the completed end-to-side splenorenal anastomosis, splenic vein, renal vein, left kidney. The exposure is through thoracoabdominal incision.

This patient it is believed is an example of extrahepatic portal bed block of congenital origin secondary to obliteration of the portal vein who was treated by splenectomy and an end-to-side splenorenal shunt. His first hematemesis occurred at the age of 17 years. He had repeated episodes until the shunt operation which was performed 6 years later. Liver function tests were normal. The initial pressure was 42 centimeters of saline and immediately following the completion of the shunt it was 23 centimeters of saline. This observation and the fact that he was well without further bleeding 5 months later is encouraging but too short a time to be sure that his condition has been completely relieved.

DISCUSSION

The shunting of the blood flow to or from a part of the body by blood vessel anastomoses is one of the more recent types of operation that has been perfected in recent years. Since Eck in 1877 first successfully performed a direct portacaval shunt in experimental animals, numerous investigations have been carried out in the laboratory to determine the

effect produced on the nutrition by such a procedure. Some of the most recent work has been reported by Whipple and his co-workers (21) in 1945. They concluded from experimental studies on dogs with a complete portacaval shunt so that only the blood from the hepatic artery reached the liver that there were all sorts of gross and histological changes in the liver. At times they noted in their animals, evidence of some functional abnormalities of the liver. A dog properly fed was found to tolerate such a shunt for 1 to 8 years and appear normal. Whipple (20) and Blake-more (2) have reported the successful production of similar portacaval shunts in human patients with apparent benefit of the portal hypertension and general improvement of the patients' condition but the effect on these individuals over a long period of time is awaited with much interest.

In our clinic some other type of shunt has been considered more desirable for two reasons. First the experimental evidence on animals, which of course is not conclusive for humans, indicates that there is some disturbance of liver metabolism. It seems advisable

to us if possible to produce some form of shunt which will not cause all the portal blood to bypass the liver. Since there are no valves in the portal vein or its tributaries it is possible to reverse the flow of blood in them. For this reason various types of venous shunts can be performed as demonstrated in this report. The second reason the direct portacaval anastomosis is not preferred is a practical one. In a number of our patients it has been impossible to isolate the portal vein because of the extreme vascularity in the region of it. For example, in Cases 4, 10, and 14 search for the portal vein had to be discontinued because of extensive hemorrhage. One of these patients, Case 4, even died as the result of the exploratory procedure. In Case 10 the common and cystic ducts were divided necessitating a cholecystectomy and a choledochojunostomy performed according to the method described by Allen. In another patient, Case 3, although the anastomosis was completed the hepatic artery was apparently damaged and as a result death followed secondary to thrombosis of the hepatic artery. On theoretical grounds and as a result of these practical experiences, namely the inability to perform a direct portacaval anastomosis in a number of cases and the danger of injury to such structures as the hepatic artery and the common bile duct, it seems to us that some other shunt is preferable if it will reduce the portal hypertension.

The operation of choice for portal hypertension whenever possible in our opinion at the present time should be a splenectomy with an end-to-side splenorenal anastomosis with preservation of the kidney (Fig. 2). Cases will be encountered in which this will not be possible, such as in patients who have had a previous splenectomy and rarely in a patient with splenic vein thrombosis in whom splenectomy alone will suffice. There are a number of reasons worth enumerating why the above type of procedure is preferred. First it produces a partial shunt of the portal blood flow so that the liver is not completely bypassed. Second from our observations this type of shunt appears to lower satisfactorily the portal hypertension. Third splenectomy reduces the arterial inflow to the portal area by approximately 40 per cent and thereby aids in reduc-

Fig. 3. An artist's drawing to show the position of the patient on the operating table. The line of incision is shown. It is midline through the bed of the tenth rib forward to the midline of the abdomen just above the umbilicus.

ing the portal hypertension. Fourth removal of this organ also divides many of the collateral channels which feed the esophageal varices so that the venous pressure and the blood flow through them will be diminished. Fifth there are no vital structures in the left upper quadrant of the abdomen, the region through which the surgical approach is made for this type of shunt, similar to the common bile duct and the hepatic artery, which lie in such close proximity to the region of the portacaval anastomosis. This point is of great practical importance since in either type of shunt operation structures are obscured by bleeding from innumerable small collateral venous channels. An error of a few millimeters in the region of the gastrohepatic ligament while searching for the portal vein may result in a fatality or prevent the successful construction of the anastomosis, whereas in the splenic area one at least has the peace of mind that such a catastrophe is less likely to occur as the margin of safety in this region can be measured in centimeters rather than millimeters. The practical value of the thoracoabdominal approach (Fig. 3) cannot be overemphasized in the exposure of the spleen, the kidney and their vessels.

Another advantage of the end-to-side type of splenorenal anastomosis is that the left kidney is not sacrificed. It is recognized that a single kidney is sufficient for the bodily needs under normal conditions, but in patients as critically ill as some of the portal hypertension cases it seems to us advisable to save this organ rather than sacrifice it. That this may

Fig. 4. An artist's drawing to show the portacaval shunt utilized. The splenoportal end-to-side anastomosis is preferred, but in cases that had had previous splenectomies, Cases 8 and 9, superior mesenteric and inferior vena cava and an inferior mesenteric and left ovarian anastomoses have been used respectively with apparent relief of the portal hypertension.

be of considerable practical importance in operations of the magnitude of these is demonstrated by Case 10. Even with two kidneys the nonprotein nitrogen level rose from 15 milligrams per cent to 102 on the sixth postoperative day and despite an adequate fluid intake the renal output was only 400 to 500 cubic centimeters for several days. The blood chemistry and urine volume returned to normal levels after the second postoperative week. This patient it can be readily seen was so close to renal failure following this operation that it certainly is within the realm of possibility that if his left kidney had been sacrificed he would not have survived.

The end-to-side type of anastomosis in addition to preserving the kidney we believe has the advantage that it is less apt to become thrombosed. This opinion was based chiefly on the fact that the flow of blood in the renal vein might have a sucking effect at the site of anastomosis, thus lessening the possibility of thrombosis. The results of the recent experimental work by Johns and by Blalock (5) lend support to this opinion as they found utilizing the suture method of anastomosis that the incidence of thrombosis was 10 per cent in the end-to-side type while with the end-to-end it

Fig. 5. An artist's drawing to show the method of suturing the end of the splenic vein to the side of the renal vein. Suture 1 is a stay suture and suture 2 is a running mattress type placed to evert the edges. It is tied to additional stay sutures at the other points in the circumference of the anastomosis to prevent a pinching effect.

was 27.3 per cent. The suture method of anastomosis described by Blalock (6) is preferred to the nonsuture technique of Blakemore and Lord (3) utilizing the vitallium tubes, since there is less danger of thrombosis with the former. Blalock (5) and Johns performed a comparable series of end-to-end splenoportal anastomoses in animals with the two methods. They reported an incidence of thrombosis of 27.3 per cent in the suture group and 72.8 per cent in the nonsuture group. These facts seem significant and perhaps are due in part to the fact that a large foreign body is left in close proximity to the vein wall. Another reason may be that it is not necessary to dissect free as much of the splenic vein with the suture method as with the nonsuture method. For this reason the vasa vasorum of the vein wall are less disturbed. This tends to protect the intima from degeneration which if it occurs favors thrombosis as pointed out by O'Neill. Up to the present time none of our cases has become thrombosed as far as is known. The anastomoses in the 4 patients who died were all patent. They survived such a short time however following the operation, one cannot be sure they would have remained open indefinitely. However the absence of further esophagogastrointestinal bleeding in the surviving patients with the exception of Case 14 is encouraging. The technique of suturing the veins together is similar to that described by Blalock (6) for the arterial shunt operations in the treatment of the tetralogy of Fallot. Care

TABLE II.—RESULTS IN THE TREATMENT OF PORTAL HYPERTENSION WITH SHUNT OPERATIONS
MASSACHUSETTS GENERAL HOSPITAL 1945-1947

Intrahepatic Type

Case No.	Age Sex	Type of shunt operation	Date of operation	Postoperative period with out bleeding	Varices still present by ray	End result & date
1	45 F	Splenectomy nephrectomy end-to-end splenoportal	3 6 45	20 mos	Yes	Alive
2	45 M	Superior mesenteric to inferior vena cava	45	—	—	Dead
3	55 M	Portal vein to inferior vena cava	8-46	—	—	Dead
4	42 M	Portal vein to inferior vena cava (attempted)	8 9-46	—	—	Dead
5	52 M	Splenectomy end-to-side splenoportal	9-46	—	—	Dead
6	54 M	Splenectomy end-to-side splenoportal	4 7 47	—	—	Dead
7	51 M	Splenectomy, end-to-side splenoportal	6 1 47	20 mos	Yes	Alive

Extrahepatic type

8	28 M	Superior mesenteric to inferior vena cava	9 9 47	20 mos	Yes	Alive
9	6 F	Splenectomy end-to-side splenoportal	6 4 46	4 mos	Yes	Alive
10	30 M	Splenectomy end-to-side splenoportal	6-8 46	4 mos	Yes	Alive
11	20 F	Inferior mesenteric to left ovarian vein	7 3 46	13 mos	Yes	Alive
12	65 M	Splenectomy end-to-side splenoportal	47	7 mos	N't checked	Alive
13	45 F	Splenectomy end-to-side splenoportal	7 47	6 mos	N't checked	Alive
14	F	Inferior mesenteric to left adrenal vein	3 9 47	Bled 4 mos	Yes	Alive
15	J M	Splenectomy end-to-side splenoportal	3-1 47	5 mos	Not checked	Alive

must be taken not to narrow the anastomotic opening by drawing the continuous suture too tightly. Interruption of it at three points in the circumference of the anastomosis is advised to prevent too much of a pursestring effect. The suture is placed so that the edges are everted and an intima-to-intima approximation is obtained. A No. 00000 braided silk suture on a No. 9 curved atraumatic type of needle is used (Fig. 5). A detailed description of the complete operative procedure has been published recently by one of us (12).

The function of the left kidney as shown by intravenous pyelography has not been damaged by the procedure. The renal artery was occluded for periods of 18 to 35 minutes as a rule while performing the splenoportal anastomosis. Occlusion of this vessel may not be necessary but it seemed best to do it and so avoid a high degree of back pressure on the renal vascular system.

The results obtained in the group of patients with extrahepatic portal bed block have been more satisfactory than in the intrahepatic group (Table II). In the former 7 patients out of 8 have not bled since the shunt was performed over periods varying from 5 to 22

months. Five of these patients had splenectomy with an end-to-side suture type of splenoportal shunt with no bleeding for 5 to 14 months. The 3 others had had previous splenectomies so that in them the following anastomoses were performed respectively: (1) superior mesenteric vein to inferior vena cava with no bleeding for 22 months; (2) inferior mesenteric vein to left ovarian vein with no bleeding for 13 months; (3) inferior mesenteric vein to left adrenal vein with bleeding again after 4 months. The results in these cases are encouraging except in the last one. The veins used in this case were so small it was thought they probably would thrombose as apparently has happened. The fact a previous splenectomy had been performed on this patient may eventually result in her death since it now seems impossible to perform a satisfactory shunt. There were no deaths in this group so the operative mortality was zero per cent.

The results were not as satisfactory in the intrahepatic group (Table II). Only 2 of the 7 patients survived making a mortality rate of 71 per cent. One of the surviving patients, Case 1, has been 29 months without bleeding the longest period of both groups. She was

operated on by Richard H Sweet and an end-to-end nonsuture vitallium tube anastomosis was performed. The other surviving patient Case 7 has been done only a period of 3 months. The deaths in the other patients of this group it is believed can be best explained by the fact that all of them Cases 2, 3, 4, 5 and 6 were extremely ill patients prior to operation. All had extremely sick livers. They all were prepared as thoroughly as possible but because of their severe liver disease they could not withstand such long surgical procedures. Two of them Cases 4 and 7 succumbed from postoperative hemorrhage in part due to the citrate solution used in the blood transfusions. It is believed that patients with such severe liver disease are unable to metabolize sodium citrate as well as the ones with normal livers. All of them except Case 6 were treated conservatively for several years for repeated esophagogastrintestinal hemorrhages, so that when the shunt operations were performed the general condition of them was extremely poor. It would seem advisable, therefore in view of the good results obtained in the younger group with extrahepatic block and also in the two cirrhotics, Cases 1 and 7 who were in good condition that a splenectomy and an end to-side splenorenal shunt should be recommended before the patient becomes depleted from multiple hemorrhages.

CONCLUSIONS

1 The development of the portacaval shunt type of operation represents a new chapter in the treatment of portal hypertension. It apparently prevents serious hemorrhage from esophageal varices, although they may still persist by roentgenographic examination and in addition may improve the liver function. Further observation of the cases reported is necessary to determine the true value of the procedure.

2 Splenectomy and the suture type of end-

to-side splenorenal anastomosis with preservation of the kidney performed through a thoracoabdominal incision are recommended as the most satisfactory operative procedure in cases, especially for extrahepatic portal bed block in which the spleen has not been previously removed.

3 Anastomosis of the superior mesenteric vein to the inferior vena cava and of the inferior mesenteric vein to the left ovarian vein has been utilized with apparent success, in 2 patients who had had the spleen previously removed.

4 Direct anastomosis of the portal vein to the inferior vena cava may frequently be impossible due to the extreme degree of vascularity in the region of the gastrohepatic ligament.

5 The results in 15 patients treated by various types of portacaval shunts have been more satisfactory in extrahepatic portal bed block than in the intrahepatic type.

CHILDBEARING IN THE TWILIGHT OF THE REPRODUCTIVE PERIOD

M EDWARD DAVIS M D F.A.C.S and ARTHUR SESKI M D Chicago Illinois

AGING is a universal phenomenon of all life. No sooner is one born than he or she begins to age. Individuals grow old at varying rates some rapidly and others more slowly. Disease of vital structures hastens the process of aging. In the last decade the profession has become acutely interested in old age for the ever increasing length of life has suddenly thrust upon us the problems of the elderly. The specialty of geriatrics has many new devotees. However one of these new specialists so aptly defined this newest problem as beginning at birth and ending at the grave.

The reproductive function unlike the other physiologic functions begins in the middle teens and ends in the fifth decade. There are few authentic records of childbirth in the fifties. In over 50 000 deliveries at the Chicago Lying in Hospital only 2 women of 46 and 2 of 48 gave birth to children. Reproduction in the human race has been limited by nature to the first half of the life cycle thereby emphasizing the fact that it is a function of youth and not middle age. Much has been written about pregnancy and labor in the elderly primipara the woman over 30 or 35 years old. However little has appeared in the literature about reproduction in women 40 years old and older. There was a classic contribution by Bethel Solomons many years ago entitled 'The Dangerous Multipara' in which he emphasized the hazards of pregnancy and delivery in women who had many babies. However this study was prompted by the frequent question raised by patients "I am nearly 40 years old. Do you think it is safe for me to have a baby, or as the case may be, "another baby for my family has grown up and I would like another child to raise?" These are pertinent questions and physicians are expected to know the answers.

In an attempt to answer them intelligently the authors decided to study the pregnancies labors and recovery periods of 1 000 women 40 years and older delivered at the Chicago Lying in Hospital and to compare these with the hospital statistics covering all deliveries during this same period wherever possible. In order to study 1 000 consecutive pregnancies in women 40 and over it was necessary to include the years 1927 to 1944. The study comprises 1 011 patients in this category. During this same period we delivered a total of 52 128 women at the hospital. The incidence of pregnancies in women 40 years and older is 1.94 per cent. Most of these 841 or 83.2 per cent were multiparas and only 16.8 per cent primiparas. An interval of at least 10 years had elapsed since the last baby was born in 152 multigravidas 18 per cent of this entire group.

In a study of this type it is necessary to present many statistical tables. These may be valuable for those individuals who have a special interest in the problem. However for most readers who find statistical studies laborious to digest we will draw a few interesting conclusions from these data.

In Table I it will be seen that 50 of the pregnancies ended in abortions an incidence of 4.9 per cent. This is higher than the hospital incidence although neither figure is representative of the population at large. In all likelihood all women with spontaneous abortions do not enter hospitals. In many instances they may not be aware of an early abortion for it may manifest itself only in an irregularity of the menstrual function. Such irregularities are rather common at this time of life. Few induced abortions enter the Chicago Lying in Hospital so that the incidence of criminal abortions at this age period cannot be gleaned from our data. All that can be concluded is that spontaneous abortions are more frequent in women of 40 and over than in the general hospital group.

From the Department of Obstetrics and Gynecology of The University of Chicago and The Chicago Lying-in Hospital.

TABLE I — TOTAL DELIVERIES 1927-1944

	Women 40+ years						Hospital	
	Primiparas		Multiparas		Total			
	N	Per cent	N	Per cent	N	Per cent		
Pregnancies	70	16.8	841	83	101	94	2.128	
Births	64	7	796	8	960	84	8%	
Abortions	3	3	43	9	46	9	0%	
Ectopic		6					36%	
Infant mortality	12	9.3	77	9.8	89	9.3	2.5%	
Neonatal	7	4.8			3	1.6	0	7%
Maternal mortality					2	4	47	7%

It is of interest that only 1 ectopic occurred in this group and that 1 in a primipara. The low incidence of tubal pregnancy may mean that if complete tubal occlusion is not present a pregnancy will occur earlier in life.

PREGNANCY

The complications of pregnancy are listed in Table II. As we might expect the most frequent complications in women 40 years and older concern the vascular renal system. Aging manifests itself first in the circulatory organs and the old adage that "you are as old as your arteries" has more than a grain of truth. Circulatory diseases exclusive of the toxemias of pregnancy were three times as common as in the general hospital group 13.4 per cent compared to 4.6 per cent. This group includes heart disease, thrombophlebitis and phlebotrombosis, extensive varicosities, productive

TABLE II — COMPLICATIONS OF PREGNANCY

Severe		6			3	3	
Total					147	14	7

of marked symptoms and miscellaneous less common conditions. There was an increase in gastrointestinal complications in the women 40 years and older although interestingly enough, these were almost entirely confined to the multipara. These complications likewise increase in frequency with aging so that pregnancy probably contributed little to this increase.

The toxemias of pregnancy are directly or indirectly the result of gestation. In Table III it will be seen that the total incidence of these pregnancy complications was 24 per cent in women 40 years and older whereas the general hospital incidence is 7.1 per cent. Thus, the elderly gravida has three and one-half times the hazard of developing a toxemia of pregnancy than the average patient.

Pre-eclampsia and eclampsia are the true toxemias of pregnancy in the sense that they are caused by the pregnancy. Aging must be an important predisposing cause for the development of this pregnancy toxemia for the incidence in the group of elderly patients is three times that in the hospital group. The typical pre-eclamptic is a woman who has a normal blood pressure and kidney function prior to the onset of pregnancy. Sometime in the last trimester of pregnancy she develops fluid retention and excessive weight gain, hyperten-

TABLE IV — PLACENTA PREVIA

sion and albuminuria. She usually is a nulli gravida. However most of these patients were multiparous women. We must assume that aging conditions the vascular renal system so that it is more vulnerable for whatever the etiologic agent or set of circumstances which induce pre-eclampsia and eclampsia.

Hypertensive and vascular renal disease is a manifestation of aging. Pregnancy influences these conditions adversely. In the multi gravida each pregnancy may add to the residual damage so that childbearing may add a considerable hazard in the woman who has reached middle life. Abruption placentae in intrauterine death of the fetus, failure of normal fetal growth and kidney failure are all undesirable sequelae.

Placenta previa is essentially a complication of the last trimester of pregnancy. It represents the unplantation of the fertilized ovum in an abnormal site within the uterine cavity. At first glance it would appear that aging should not influence the incidence of this complication. However clinical experience has brought out the fact that multiparity increases the frequency in direct proportion to the number of births. How pregnancies alter the transport mechanism of the fertilized ovum or the uterine environment to favor implantation near the cervical os is not known. However the incidence of placenta previa was 2.9 per cent in women 40 and older, four times the hospital incidence of 0.79 per cent. These occurred predominantly in multigravidas (Table IV).

The high incidence of hypertensive and vascular renal diseases in women 40 and over would predispose to an increased incidence of

TABLE V — ABRUPTIO PLACENTAE

abruption placentae. The incidence of 2.1 per cent was almost three times the hospital incidence of 0.83 per cent (Table V).

LABOR

Labor terminated uneventfully in the majority of women 40 years and older and the incidence compared favorably with our hospital statistics. At least half of the primigravidas delivered spontaneously or were delivered by simple low forceps. Age alone should not be considered as the motivating factor in deciding against a normal delivery. However the woman having her first baby at the end of her reproductive period must be given intelligent care. Often it is her only opportunity for a child. Furthermore the incidence of the complications of pregnancy, the toxemias, placenta previa, and abruption placentae are all increased so that they must enter into the choice of the best method for delivery. Thus it is not age alone but age plus these complications of pregnancy occurring with greater frequency because of age that determines the

TABLE VI — TERMINATION OF PREGNANCY

Other	4	7		8.8	

mode of delivery. It is not surprising therefore that 31.5 per cent of primiparas were delivered by cesarean section whereas the hospital incidence is 4.4 per cent (Table VI).

The incidence of cesarean section in multiparous women was likewise increased 9.5 per cent. This increase resulted from several factors. First and foremost was the marked increase in the complications of pregnancy particularly the toxemias. Many of these patients were delivered prior to the end of pregnancy in order to halt the progress of the disease or to increase the likelihood of a living child. In some of these women abdominal delivery in addition afforded an opportunity to terminate the reproductive career. However this has not been the primary objective of cesarean section in the last 7 or 8 years. Placenta previa and abruptio placentae may be better treated by abdominal delivery than by other methods. The elderly multipara occasionally not often develops an abnormal labor mechanism, a faulty fetal position or the size of the baby exceeds the capacity of the pelvis. Cesarean section may offer the most conservative termination in some of these circumstances. It will be noted in Table VI that the incidence of version and extraction was likewise increased as a result of some of these factors.

Table VII lists the indications for cesarean section and it can be seen that the percentage of cesarean sections done for the major complications did not differ much in the two groups. Although 32 per cent of our abdominal deliveries are for cephalopelvic disproportion and dystocia, 30.4 per cent of the sections

TABLE VIII.—INCIDENCE OF CESAREAN SECTION

Women 40+ years	Total 18-43 32 per cent		Hospital (1917-1947) Per cent
	No.	Per cent	
First section	98	78.7	61
Second section	23	17	13.4
Third section	5	3.9	2
Fourth section	3		
Maternal mortality		5	66
Cesarean hysterectomy	26	20.3	7.4
Vaginal cesarean section		2	3

in the group of women 40 years and older were done for this indication. There is a slightly higher incidence in the other complications listed because of the increased incidence of these conditions. This statistical table emphasizes the fact that age alone was not the primary factor in the choice of abdominal delivery but it contributed in the ultimate decision.

A breakdown of the abdominal deliveries is presented in Table VIII. The high incidence of cesarean hysterectomies is noteworthy. There were three times as many cesarean hysterectomies in women 40 years and older, 20.3 per cent as in the general hospital group, 7.4 per cent. This can be accounted for by the increased frequency of neoplasms at this period of life, the increase in pregnancy complications such as abruptio placentae and placenta previa, as well as the decreased value of the uterus at the end of the reproductive period. The choice of cesarean hysterectomy as a means of abdominal delivery in women late in life in whom reproduction is no longer possible or desirable has been made more and more frequently on our service at the Chicago Lying In Hospital. It is an excellent elective procedure and when done properly does not increase the risk of abdominal delivery. The patient is relieved of many of the complications associated with the menopause. The fear of cancer of the corpus is likewise removed. It is a procedure which should find increased use by specialists.

The duration of labor in women who were delivered vaginally was approximately the same in both groups of patients (Table IX). If the length of labor is to be used as a guide, aging did not alter the course of natural labor. The multigravida of 40 years and older did not

TABLE IX.—DURATION OF LABOR

Women 40+ years							Hospital
	Primiparas		Multiparas		Total		
	N	Per cent	N	Per cent	No.	Per cent	
	Less than 4 hrs.		5 to 10 hrs.				
Short	46	25.0	70	23.8	75	23.0	37
Average	0-4 hrs.		5 to 10 hrs.				
	48	40.6	400	60.5	457	55	54.5
Long	21 hrs. +		30 hrs. +				
	24	20.5	48	5.7	7	8.6	8.9

have a longer labor than her younger sister. There were however many more complicated labors in the older group of mothers for in Table VI it will be noted that whereas the incidence of mid forceps is 4.0 per cent in our hospital 15.2 per cent of the primiparas were delivered by mid forceps operations. These procedures were indicated largely because of failures in the labor mechanism. The occiput failed to rotate anteriorly resulting in a transverse arrest of the head or an occiput posterior position the forces of labor were unable to bring the head onto the perineum or the soft parts were abnormally rigid. These labor complications can be charged directly to the age of the woman having her first baby.

One observation that is difficult to explain is the increase in breech presentation in the group of elderly women. The incidence of breech in the primiparas was 7.4 per cent and the multiparas 5.4 per cent in contrast to the hospital figure of 4.4 per cent. There was an increase in the transverse presentations among the multiparas which was to be expected 1.1 per cent compared with a hospital incidence of only 0.2 per cent.

PLACENTAL STAGE OF LABOR

The placental stage of labor was marked by an abnormal blood loss in a greater number of women 40 years and older than in the hospital group as a whole. The incidence of postpartum hemorrhage was 3 per cent in the primiparas and 7.1 per cent in the multiparas whereas the hospital average during this entire period was 7.7 per cent. It is not surprising that more of the multiparas had an excessive blood loss

TABLE X.—WEIGHTS OF BABIES

for difficult labors and operative interventions increase the hazard of uterine atony. Many of these patients were delivered prior to the use of ergonovine administered intravenously at the end of the second stage of labor. There has been a phenomenal decrease of excessive blood loss during the placental stage since the introduction of present day management of this important phase of delivery.

THE INFANT

In Table X there is a comparison of the birth weights of babies born to mothers 40 years and older and the entire hospital group. In general it can be said that there are no significant differences in the two groups. It has been observed in one of our previous studies that babies tend to become progressively larger in each pregnancy until the fourth baby is delivered following which the birth weight tends to level off. This observation is confirmed in this study for 12 per cent of elderly multiparas gave birth to babies weighing from 4,000 to 4,500 grams and 5.5 per cent weighed more than 4,500 grams. This is more than twice the incidence of babies weighing over 4,000 grams born to all mothers at the hospital.

Table XI is an analysis of the fetal mortality in the various weight groups. There is an increased number of premature babies weighing 1,500 to 2,500 grams in the group of women 40 years and older 9.6 per cent in contrast to a comparable hospital incidence of 6.1 per cent. There is likewise a higher fetal mortality in this same group 200 per 1,000 live birth in

TABLE VI.—INFANT MORTALITY IN RELATION TO BIRTH WEIGHT AND HOSPITAL STATISTICS

Birth weight in grams	Women 20+ years		Hospital per cent	Women 40+ years		Women 40+ years		Hospital rate per 1000
	Total births			Stillbirths N	Neonatal deaths No	Total No	Rate per 1000	
	No	Per cent						
Prevalable 200-500			7	2			900	944
Premature 500-1,000	19	3	8.9	3	9	44	400	125
1,000-1,500		7	8		5	17	2000	256
1,500-2,000	93	9.6	6	7	7	14

5,000+	26	7					27	24
Total	974	100	200	5	20	90	91	11

comparison to the hospital average of 158. This is easy to account for in the increased incidence of maternal complications among the mothers. The extremely high incidence of the toxemias of pregnancy 24 per cent, the increased incidence of complications of the last trimester associated with hemorrhage, and the circulatory disturbances all provide great hazards for the babies. Premature deliveries necessitated by these maternal complications resulted in many premature babies which were normal but did not survive because of their prematurity. Some of them succumbed as a result of the damage they incurred because of the maternal complication.

Babies weighing over 2 500 grams likewise fared less well in the group of elderly women

TABLE VII.—MORBIDITY

Women 40+ years							Hospital

Inf. epiglottitis		4					
Mastitis		6					2
Other		7	9	4	3	1	

than in the general hospital group the rate was 42 in contrast to 13 per thousand live births. For the entire group the rate was 91 in comparison to the hospital rate of 35 per thousand live births. The mother 40 years or older who is having a baby has a 1 out of 10 chance of leaving the hospital without a baby. This high fetal loss is worth considering in evaluating obstetrical problems of elderly women.

Women nearing the end of their reproductive periods often inquire as to the possibility of an abnormal baby. Penrose in the *Journal of Mental Sciences* reported that the mean age of the mothers of 224 Mongolian babies was 37.4 years. Furthermore, the probability that a mother will give birth to a Mongolian child is more than doubled for every 5 years after the age of 25. He noted an excess of Mongolians in primigravidae and in multigravidae after their seventh birth. In our material there were 6 Mongolian babies diagnosed while in the hospital. It is more than likely that if a careful follow up were instituted this number may be doubled for a diagnosis may be difficult or impossible during the first 10 days of life. It is of interest to note that they were divided equally between primiparas and multiparas although in our series the former comprised only one fifth of the total number.

Other anomalies of the fetus were more numerous in women 40 years and over. Two babies

TABLE VIII—MATERNAL DEATHS IN WOMEN 40+ YEARS

Unit number	Age, gravidity, and para.	Diseases	Weeks gestation	Termination of pregnancy	Complications

had spina bifida malformations 3 had major gastrointestinal anomalies and 16 had a variety of malformations, some major and some minor. There were a total of 27 babies with malformations of one type or another an incidence of 2.7 per cent compared with our hospital incidence of 1 per cent. The increased hazard of a congenital anomaly in the baby cannot be dismissed lightly in women of 40 and older.

MATERNAL MORBIDITY AND MORTALITY

The maternal morbidity in the group of women 40 years old and older was comparable to the entire hospital group (Table VII). Tremendous changes have taken place in obstetrics during the 17 years covered by this study so that comparisons are difficult to make. However, no unusual puerperal complications can be ascribed to this special group of women.

There were 4 maternal deaths in the group of women reported in this study. All of these deaths occurred prior to 1931. A summary of the histories is presented in Table VIII. The senior author has recently reviewed the maternal mortality in the Chicago Lying in Hospital. By our own criteria at least 3 of the 4 deaths were preventable by present day standards. The more intelligent obstetrical management of obstetric patients, the increased safety of cesarean section and the use of antibiotics have decreased maternal mortality phenomenally in recent years. In the country at large but especially in the well conducted maternities maternal mortality is decreasing year by year. We can learn nothing from these 4 deaths for they are one milestone in obstetric progress. They need not happen in 1947.

CONCLUSION

This study comprises a review of the obstetrical histories of 1,011 women 40 years old and older who were cared for at the Chicago Lying in Hospital during the years 1927 to 1944 inclusive. It was designed to determine how aging can influence the reproductive function. The complications of pregnancy were much more common in this special group of patients than in the general population of the hospital. One out of every 4 women developed a toxemia of pregnancy. Placenta previa and abruptio placentae increased materially. The circulatory complications other than the toxemias much more common in middle age than in the young increased the hazard of childbearing. Labor was marked by a marked increase in operative interventions as a result of the pregnancy complications and the age of the group.

Babies born to women 40 years old and older shared in the greatly increased hazards of childbearing. One out of every 10 mothers failed to take a baby home with her when she left the hospital. The high fetal mortality was the result of an increased number of premature babies, an increased number of congenital abnormalities and a higher incidence of fetal damage because of the greatly increased number of pregnancy complications.

Nothing has been said about the postdelivery recovery of these women and their babies. It was difficult to glean accurate information about many phases of this important period of childbearing. It has been our experience that elderly women recover more slowly than younger ones. They are more likely to have

minor complaints such as residual backache. However the opposite is likewise true. We have all seen women who have acquired the physical and mental attributes of middle age transformed into young women by childbirth with the zest and sparkle that is youth.

The babies of women of 40 and over deserve more study. The adjustment of the mother to the newborn is usually more difficult in older women. The youngster takes to her baby naturally. They grow up together. This relationship must result in a good psychological background for the growing child. The problems of child care appear very differently to the mother of 20 and to the one of 40. These mother and child relationships are very much in the limelight today.

We have not been able to evaluate the residual damage to the mother who develops serious complications of pregnancy and labor. Do the toxemias cause irreversible pathology that may handicap or shorten the mother's life? Does pregnancy hasten the inevitable progress of some of the circulatory diseases? These and other questions are very important particularly in the multiparous woman with children who need their mother to help them grow up normally and happily. These are important questions that should be answered in a study of childbearing late in life.

We can conclude from our study that many hazards beset the woman and her baby when childbirth takes place at the end of the reproductive period. These hazards are real and result in increased morbidity and mortality for both. Aging involves primarily those organs which play a vital rôle in reproduction: the vascular system, the heart and the kidneys. Pregnancy adds to the strain placed upon these structures. Indeed we can once more reiterate a pertinent conclusion reached by Eastman that youth is the mother's best ally.

CARCINOMA OF THE LIP

A Review of 563 Case Records of Carcinoma of the Lip at the Pondville Hospital

JAMES E. CROSS M.D., EUGENE GURALNICK, M.D. and
ERNEST M. DALAND M.D. F.A.C.S., Boston Massachusetts

CARCINOMA of the lip one of the most malignant neoplasms of the oral cavity is one of the most readily curable malignancies encountered in the body. Because of the prominent location it is usually brought to the attention of the patient at an early stage and therefore should be seen by the physician while still amenable to treatment. This study was undertaken in an effort to evaluate the results of treatment of all patients with carcinoma of the lip either seen in the Out Patient Clinic or admitted to the Pondville Hospital from the time of its establishment in June 1927 to December 1941. This particular period of time was chosen in order to have a complete 5 year follow up record on all the patients who received treatment.

The records of 563 patients with carcinoma of the lip constituted the series for review and consideration. These cases were 2.9 per cent of the 19,664 new patients examined in the Out Patient Department during the period covered by the study.

It was hoped that by a critical study of a relatively large series of cases certain criteria could be established from which it would be possible to outline the method of therapy most likely to be successful in a given case and to give a reasonably accurate prognosis at the outset of treatment.

ETIOLOGY

The age of the patients at the onset of the disease ranged from 25 to 91 years with the greatest incidence between 55 and 75 years. Both the median age and the mean age were found to be 62 years.

Ninety-eight per cent of the patients were males and 2 per cent were females.

From the Pondville Hospital (Massachusetts Department of Public Health) Walpole, Massachusetts.

All of the patients were of the white race. It should be noted however that very few colored patients are seen at the Pondville Hospital.

A positive Wassermann or Hinton reaction was found in 7.2 per cent of the patients examined. This is comparable to the 6 per cent reported by Hayes Martin and associates (4).

The lower lip was the site of the primary tumor in 497 patients. There were 19 tumors of the upper lip and 47 of the labial commissures. The right and left sides were involved with approximately equal frequency.

The median duration of disease at the time of the first visit to the Pondville Clinic was found to be 6 months. This figure is considered more accurate than the average duration of 17 months because the latter resulted from the fact that a few lesions were said to have existed for as long as 20 years. It is felt probable that malignant tumors superimposed upon long standing precancerous conditions account for these cases of extremely long duration.

In this connection it seems surprising that a patient will allow an obvious lesion occupying a prominent position on the lip to go untreated for such a period of time particularly since it must be seen daily in a mirror. However the growth is slow and gradual as a rule and painless if uncomplicated by infection. Furthermore it must be noted that the responsibility for delay between onset of the disease and the presentation of the patient for treatment does not rest solely with the patient. Many physicians not recognizing the true nature of the process are guilty of procrastination or inadequate and ineffectual treatment with a variety of salves antiseptics pastes or minimal doses of radiation. This is particularly unfortunate because lesions 1 centimeter or less in diameter can be treated with almost

certain assurance of complete success. It is hoped that the present-day increase in cancer consciousness will tend to eliminate some of this delay.

The size of the primary lesion was recorded in 349 cases. The great majority (76.5 per cent) of these had a maximum diameter of 2.0 centimeters or less, while 39.2 per cent measured 1.0 centimeter or less in greatest diameter. The majority of the remainder had a range from 2.1 to 5.0 centimeters in size. A small number of extensive growths measured from 5.1 to as much as 12 centimeters.

In the records studied definite information concerning both oral hygiene and the use or non use of tobacco was available in 356 cases. Of this total 335 patients were classified as habitual tobacco users. Three hundred and ten of these had either poor oral hygiene (58.1 per cent) or were edentulous (41.9 per cent). On the other hand only 21 patients used no tobacco and 18 of these had poor oral hygiene or were edentulous. Only 28 or 7.8 per cent of the entire group had a good or fair oral condition. Seventy-one per cent of those who used tobacco smoked a pipe.

The edentulous group deserves some comment. This is a separate category because its members did not fall by description into either of the other two groups. It might be argued that the edentulous patients, having no dirty or carious teeth or infected gingiva had good or at least fair oral hygiene. On the other hand it might be said that these patients had lost their teeth for the very reason that they had had poor oral hygiene.

Sixty-two patients gave a definite history of trauma prior to the appearance of the tumor. These included not only such single episodes as a cut while shaving a cigarette burn an injury in the course of tooth extraction or a burn from sparks while engaged in welding but also repeated injuries from poorly fitting dentures sharp jagged teeth or the holding of roofing nails and bristles in the mouth in daily work. None of these patients were found to have good or even fair oral hygiene. Forty-one however were recorded as having a poor oral condition and 21 as edentulous.

This is not meant to imply that single trauma is a cause of carcinoma of the lip we do

feel however that trauma superimposed upon a background of poor oral hygiene may be of some significance.

It was found that *leucoplakia* or *keratosis* of the lip was associated with carcinoma in 81 cases (14.5 per cent) of the series.

Other *unassociated carcinomas* were observed in 67 of the patients, or 11.9 per cent of the entire group. Of this number 52 patients had, in addition to carcinoma of the lip a second malignant tumor 11 had 2 other lesions, and 4 had 3 additional neoplasms.

PLAN OF TREATMENT

There has been considerable controversy in the literature concerning the treatment of choice in lip carcinoma and it is not the object of this paper to attempt to prove the relative advantage of one method of therapy over another. Suffice it to say that both radiation and surgery have their place in the treatment of carcinoma of the lip at the Pondville Hospital the emphasis has been on surgical therapy.

Examination of the patient in the Pondville Out Patient Department includes measurement of the lesion and careful palpation of the neck to determine the presence of lymph nodes. The size consistency tenderness, and mobility of any palpable nodes are noted, with particular attention to any asymmetry in the sides of the neck. On the basis of this examination a clinical impression as to the presence of lymph node metastases is noted in the record. The patient is also referred to the staff dentist for such hygienic measures as may be indicated and any necessary extractions.

Suitable patients are treated by a simple "V" excision performed under local anesthesia. The surgical treatment of the larger lesions involves a more extensive quadrilateral excision with some type of plastic reconstruction of the lip such as the one described by Daland.

It was noted that plastic procedures were carried out on 58 patients in this series this was 11.8 per cent of all patients treated. Thirty-six of these 58 patients had primary tumors involving one-half or more of the lip and multiple stage operations were performed

In a few instances Seventy four per cent of the patients requiring plastic operations achieved 3 year cure status

Although several of the patients in this series, particularly in the early years underwent excision of the lip lesion and dissection of the cervical lymph nodes at one operation it is now preferred at Pondville to bring the primary lesion under control before attacking the lymph nodes Since lymph node metastases from carcinoma of the lip occur by way of emboli rather than by lymphatic permeation *en bloc* dissections of the primary lesion and the regional lymph node bearing areas are unnecessary The short period of delay enables better evaluation of the status of the lymph nodes by allowing inflammatory nodes to become quiescent after the eradication of sepsis within the mouth and incident to the tumor itself The staff may also be more confident that the primary lesion is really controlled before dissection of the regional nodes is carried out.

After excision of a carcinoma of the lip with no clinically demonstrable metastases the patient is followed in the out patient clinic and careful examination at 3 or 4 week intervals is made for the first 6 months and at 6 week intervals for the balance of the first year During the second year return visits are made every 2 months and thereafter the interval is gradually prolonged After the fifth year if no recurrence or metastasis has been found visits are made on an annual basis Because of the frequent follow up program made possible by an active and energetic social service department it is felt that prophylactic neck dissection would not offer sufficient added benefit to compensate for the effort and operative risk involved

When neck dissection is carried out however the supraomohyoid technique described by Taylor and Nathanson (7) is in most instances the procedure of choice since it has been shown that carcinoma of the lip metastasizes primarily to the upper cervical lymph nodes. Although most of the primary metastases are included in the more limited field comprising the submaxillary and submental triangles the extension of the field of dissection to the omohyoid muscle increases the

possibility of cure without materially adding to the risk or the time involved in the operation

In cases with more extensive metastases involving the jugular chain of nodes a more radical dissection is done, and the node bearing tissues including the sternocleidomastoid muscle and internal jugular vein are removed down to the level of the clavicle

SELECTION OF CASES FOR ANALYSIS

The end result analysis is based on data recorded for 491 patients 72 cases having been excluded as unsuitable for study for one of the following reasons Some patients having received all of their treatment elsewhere had reported to our out patient clinic for diagnosis only A few patients were admitted for terminal care they were moribund on admission and were given no definitive treatment We also excluded those who had been treated elsewhere and in whom no evidence of carcinoma was found at our clinic Nine patients whose diagnosis was basal cell carcinoma of the upper lip were excluded because it was felt that these carcinomas were tumors of the skin and did not arise in the mucosa of the lip A small number of patients could not be included because they left the hospital on their own responsibility and against advice before any treatment could be started

All but 6 of the remaining 491 cases have had complete follow up either by personal visits to our out patient department or to one of the state-aided tumor clinics of Massachusetts for a period of at least 5 years The 6 patients who were lost to follow up were included in the series and counted as treatment failures. Also included in this category were 4 patients living and free of disease at present who have had treatment for recurrences within the past 3 years. All other patients who received any type of treatment whatsoever have been included in the analysis

CLASSIFICATION OF CASES

The 491 records were classified first as either primary or secondary cases The primary group includes those patients who received all their treatment at the Pondville Hospital and the secondary group those who had been

TABLE I—END-RESULT ALL CASES

Total number of cases treated	491
Clinical diagnosis only—no pathological report	84
Died of intercurrent disease in less than 3 years, inconclusive	54
	3 ⁵ 38
Remaining	353
	Number Percent
Died with disease	66 30.0
Living and free of disease but had recent recurrence (treatment failures)	4
Lost to follow up (treatment failures)	6 7
3 year cures	37 67.1
5 year cures	203 63.6

treated inadequately elsewhere for carcinoma of the lip and then came to Pondville for further treatment

These two groups were then classified according to the type of therapy the patients received at Pondville: surgery (I) radiation (II) or combined (III). Group I consists of those cases in which the course of treatment was surgical eradication of the primary lesion, regional lymph nodes and any subsequent recurrence or metastasis. Group II includes those patients whose Pondville therapy was x-ray or the topical or interstitial application of radium or radon. In group III patients were treated by the combined use of surgery and radiation.

In evaluating end results a 3 year cure was defined as one in which a patient had remained free of any evidence of carcinoma of the lip for at least 3 years following last treatment and had never subsequently developed a recurrence. A 5 year cure is one in which a patient fulfills these criteria for a 5 year period. Those who are classified as having died of intercurrent disease survived less than 3 years after their last treatment were adequately followed and were found to have no evidence of persistent or recurrent carcinoma at the time of death.

No pathological report is available for 84 patients who were treated by radiation on the basis of clinical diagnosis alone. These cases have been considered separately and are not included in the end results for all cases.

RESULTS OF TREATMENT

The total cure rate at the Pondville Hospital for all proved cases of carcinoma of the

TABLE II.—END-RESULT—CASES WITHOUT PATHOLOGICAL REPORT

Total number of cases	84
Died of intercurrent disease	1
Remaining	71
	Number Percent
Died with disease	11 30.9
3 year cures	49 69.0
5 year cures	42 65.2

lip irrespective of method of treatment, is 67.1 per cent based on the 3 year cures and 63.6 per cent based on the 5 year cures (Table I).

Inasmuch as our figures show only a slight difference between the percentages based on the 3 and 5 year cures and since this difference may be accounted for by normal loss through intercurrent disease in the age group concerned it is felt that statistically the 3 year cure rate is an adequate measure of success in treatment of carcinoma of the lip.

We do not feel however that it is statistically sound to include those patients who were treated without pathological confirmation of the diagnosis. It is nevertheless of interest to note that the results of treatment in this group (Table II) are comparable to those in the group with proved diagnoses. Many early cases as well as those with obviously advanced disease are included in this group.

Primary cases. The primary group consisted of 242 cases. The results of therapy were analyzed according to the type of treatment these patients received and as can be seen from Table III the great majority of the cases were treated surgically. Before concluding from this table that the results of surgical therapy are far superior to those obtained by radiation or by a combination of surgery and radiation, it should be pointed out again that the preferred method of treatment of carcinoma of the lip at the Pondville Hospital is surgical. Therefore while in many favorable cases patients were treated in this manner the radiologists were called upon to treat many lesions which were far advanced and no suitable for surgery. Furthermore many of the earlier and smaller lesions which were treated by radiation were not subjected to biopsy and are therefore not included in Table III.

TABLE III.—END-RESULT—PRIMARY CASES
ACCORDING TO METHOD OF TREATMENT

	No. of cases	Died with disease or treatment failure—%	3 year cures—%	5 year cures—%
Surgery	17	6.0	93.0	91.8
Radiation	34	50.0	47.1	45.3

	No. of cases	3 year cures—%	No. of cases	3 year cures—%	No. of cases	3 year cures—%
Up to	33	97.0	10	100	96	98.6
1.1 to 2	115	8.5	7	7.7	83	88.0
2.1 to 3		6.5	7	50		7.4
3 to 4	30	46.7	7	50	3	00

It was felt that by comparing a group of lesions treated by radiation with a group of lesions of similar size treated surgically a clearer picture of the relative efficacy of surgery and radiation would be obtained. A group of 67 patients was therefore selected they had had radiation therapy only many were treated without a confirmatory pathological diagnosis. No lesion exceeded 4 centimeters in greatest diameter. Since it has been shown before that the end results in cases without confirmatory pathological diagnosis are comparable (Table II) to those in the pathologically proved cases, inclusion of some of these cases seemed justified in order to obtain a series which would be statistically significant. Seventy-eight and two-tenths per cent of this selected group of radiation cases were 3 year cures 76 per cent were 5 year cures. This more nearly approaches the results obtained by surgery.

Table IV shows the effect of therapy on lesions of comparable size treated either by surgery or by radiation. As might be expected the smaller lesions show a higher percentage of curability and this holds true for tumors up to 3 centimeters in greatest diameter. The curability rates of the larger lesions are not consistent partly because of the smaller number of cases involved and partly because of the fact that the group becomes, to a certain degree self-selective i.e., the large, slowly growing lesions of low grade malignancy metastasize late, whereas more highly malignant tumors would produce fatal metastases before attaining such size. It should be mentioned that all the lesions 1 centimeter or less in diameter were observed to respond favorably to treatment, and radiation and surgery were equally effective in treating these small tumors. Two of these patients, treated surgically, were lost

to follow up and were therefore counted as treatment failures.

In considering the group given combined therapy it should be pointed out that the program of treatment planned originally included both radiation and surgery in approximately only one-half the cases. This group included those patients who had radiation therapy to the primary lesion and prophylactic or immediate therapeutic dissection of the cervical lymph nodes those who had surgery of the primary lesion and either prophylactic or therapeutic radiation (either external or interstitial) to the neck and those in whom the primary lesion was treated by electrocoagulation and radiation. The remainder of the cases fall into either one of the two following groups: patients originally treated by surgery in whom the response to treatment was unsatisfactory or in whom a recurrence of disease or late metastasis was treated by radiation or patients originally treated by radiation in whom the response to treatment was unfavorable or in whom a recurrence of disease or late metastasis was treated by surgery.

In the primary group of patients treated by surgery (Table III) there were 12 treatment failures (6.9 per cent of the cases). Of this number 2 patients now living and free of disease have had recurrences within the past 3 years. Four patients have been lost to follow up and were therefore also regarded as treatment failures. Of the 6 patients known to be dead one refused neck dissection following excision of a carcinoma of the lip and subsequently died with advanced metastases. One man, aged 83 years was seen in the follow up clinic on only one occasion following an excision of a lesion of the lip and was reported to have died of carcinoma 9 months after oper-

TABLE V.—END-RESULT—SECONDARY CASES

	N cases	Died with disease or treatment failure—%	3 year cure—%	5 year cure—%
Surgery	4	25	7	69
Radiation	43	83	69	6
Combined	5	60	20	20
Total		60.9	26	14.6

ation. A third patient died with postoperative sepsis in the neck following V excision of a carcinoma of the lip and neck dissection done at a single operation. The fourth death was due to pneumonia following V excision. The fifth patient died with recurrent carcinoma in the neck after having had a neck dissection. The sixth death was that of a known cardiac patient subject to anginal attacks. He died on the operating table and autopsy showed death to be due to advanced coronary artery disease.

Secondary cases. Many of the secondary cases had advanced lesions when first seen in the Pondville Clinic. Some had been treated with cancer paste, inadequate excision or insufficient radiation therapy elsewhere. Several were referred for treatment of metastases and for palliative therapy of advanced disease. Only those cases with proved pathological diagnoses of carcinoma of the lip were included in this study and in Table V they are classified according to the type of treatment which they received at this hospital.

With surgical treatment the 3 year cure rate was found to be 71.4 per cent while that for radiation therapy was 6.9 per cent. The apparent low salvage rate resulting from radiation therapy is again explained by the fact that the radiologists were called upon to treat most of the unfavorable cases from the standpoint of palliation only.

TABLE VII.—RELATIONSHIP OF GRADE TO RECURRENCE

Grade	Number of cases	Recurrences—%
I	178	3.5
II	6	80
III	23	30.4
Not graded	17	5.9
Total	270	13.4

COMMISSURE LESIONS

In reviewing this series of records we were impressed by the relatively greater resistance to treatment demonstrated by lesions of the labial commissures as compared to carcinomas located elsewhere on the lips. It was found that these lesions were difficult to control and local recurrences were more frequent than with other lip neoplasms. In fact it was observed that carcinomas in this location behaved identically with tumors of the buccal mucous membrane. Although these lesions were included in the computation of total end-results, it was felt that further study of them as a group was indicated. Table VI illustrates that the curability of lesions in this location is relatively low; the 3 year cure rate of 35.7 per cent is comparable to the 39 per cent local cures for carcinoma of the buccal mucosa reported by Taylor and Nathanson (7).

GRADING OF LESIONS

An attempt was made to group all lesions into one of three pathological grades. Grade I included those lesions which on microscopic section showed numerous epithelial pearls, considerable keratinization readily visible intercellular bridges, less than two mitoses per high power field and only slight variation in size and shape of cells. Those lesions classified as grade II showed rare epithelial pearls or none at all, a moderate degree of keratinization, some intercellular bridges, an average of two to four mitoses per high power field and moderate variation in size and shape of cells.

TABLE VIII.—RELATIONSHIP OF GRADE TO NODE METASTASES

Primary Cases		
Grade	Number of cases	Per cent with node metastases
I	78	6.7
II	6	33.3
III	23	34.8
Not graded	17	35.3
Total	270	14.3

TABLE IX —RELATION OF GRADE TO CURABILITY—ALL CASES

Grade	No. cases	Died with disease or treatment failure—%	3 year cures—%	5 year cures—%
I	204	4.5	75.5	71.6
II	86	4.9	58	55.6
III	23	51.5	48.5	46.0
Not graded	30	43.3	56.7	56.7

Grade III lesions showed no epithelial pearls only slight keratinization no intercellular bridges an average of over four mitoses per high power field, and marked pleomorphism with the presence of tumor giant cells. The least well differentiated portion determined the pathological grade in those cases involving areas which apparently differed in degree of malignancy.

Thirty lesions out of a total of 407 biopsied cases, were found unsatisfactory for grading. Inspection of Tables VII and X indicates that the ungraded primary lesions have a low recurrence rate and a curability comparable to the grade I tumors while the ungraded secondary lesions seem to approach the grade II lesions in respect to these two factors. The difficulty in grading some of the secondary tumors was due to distortion of the cells resulting from previous treatment.

LOCAL RECURRENCES IN RELATION TO GRADE

We have defined recurrence as the appearance of carcinoma at or near the site of a lesion which had previously responded favorably to treatment. In many cases it was extremely difficult to differentiate between local recurrence and the appearance of a new and independent tumor and whenever there was any doubt on this point the second lesion was termed a recurrence. Forty three cases or 15.4 per cent, of the 279 primary cases had recurrent disease at some time after treatment (Table VII). Six cases lost to follow up were excluded in calculating the recurrence rate. Fifty per cent of the patients who had recurrent local disease ultimately achieved 5 year cure status.

Fifty-eight per cent of the recurrences were noted in less than 2 years and two-thirds of these appeared within 4 months. The remain-

TABLE X —RELATION OF GRADE TO CURABILITY
Primary Cases

Grade	No. cases	Died with disease or treatment failure—%	3 year cures—%	5 year cures—%
I	58	6	87.4	84.8
II	50	32	68	65
III		33.3	66.7	65
Not graded	3	3.4	84.6	84.6

Secondary Cases

I	45	66.6	33.3	31.8
II	36	33.6	44.4	42.0
III		83.3	16.7	6.7
Not graded	7	64.7	35.3	35.3

ing 42 per cent (18 cases) developed recurrence in from 3 to 10 years. Although we have classified the patients in the latter group as recurrences it is probable that many of the cases were new tumors for these patients were under regular observation during the interim. Nearly all the late recurrences were grade I lesions. It was noted that grade II and grade III carcinomas tended to recur within the first 4 months after completion of treatment and rarely after more than 18 months. In the low grade lesions 5 year cures were ultimately effected in 80 per cent of the recurrences whereas only 25 per cent of the recurrent grade II and grade III lesions were cured.

One fifth of the recurrent tumors were of a higher pathological grade than were the primary tumors. This is doubtless explained on the basis that the most malignant portion of a tumor is more likely to metastasize and that the microscopic sections do not necessarily pass through the most malignant areas.

METASTASES IN RELATION TO GRADE

Metastases to lymph nodes occurred in 40 or 14.3 per cent of the primary cases. It was found that the occurrence of regional lymph node metastases as well as the rate of recurrence was directly proportional to the grade of malignancy of the primary cancer. This relationship is shown in Table VIII. It was also noted that 7 lesions metastasized as tumors of a higher pathological grade than the primary carcinoma.

TABLE XI—CURABILITY OF NODE METASTASES

Grade	All cases with positive nodes		Primary cases with positive nodes	
	No. cases	5 year cures—%	No. cases	5 year cures—%
I	7	29.6	20	70
II	5	20		6
III	16	4.3	7	24.2
Not graded	5	6.2	6	26.7
Total	33	1	33	2.4

CURABILITY IN RELATION TO GRADE

Since the grade I carcinomas are less likely either to recur or to metastasize than tumors of higher pathological rating. It might be expected that they would also respond favorably to treatment in a higher percentage of cases. This is indeed true and Table IX shows the relationship of grade of malignancy to curability for all lesions treated. Table X illustrates the same relationship with primary and secondary cases analyzed as separate groups.

REGIONAL METASTASES

Metastatic carcinoma in regional lymph nodes was found in 113 patients. This group included patients with metastatic carcinoma proved by biopsy as well as several cases in which the patient ultimately died with gross tumor in the neck, secondary to cancer of the lip but unconfirmed by biopsy.

Metastases occurred with greatest frequency (32.1 per cent) in lesions of from 12 to 24 months duration. The rate of occurrence then decreased to 14.7 per cent in lesions of from 2 to 10 years existence. No metastases were noted in the cases of 10 or more years duration and this might be expected inasmuch as the tumors were of low grade malignancy and the group as a whole self selective, i.e. highly malignant lesions untreated for such a period of time would have resulted in early death. It was also found that the frequency of occurrence of metastases was in direct relationship to the size of the primary tumor. There was no regional node involvement when the primary lesion measured less than 0.5 centimeter in diameter but 14.9 per cent of the patients with lesions measuring up

TABLE XII—CURABILITY OF OPERABLE NODE METASTASES

Grade	All cases with operable positive nodes		Primary cases with operable positive nodes	
	No. cases	5 year cures—%	No. cases	5 year cures—%
I	14	50	7	24.6
II	5	22.2	7	28.6
III	8	5	5	20
Not graded		30		100
Total	30	2.9	29	30

to 2 centimeters in diameter developed cervical node metastases. Metastatic regional involvement was also noted in 23.8 per cent of the patients whose tumors measured from 2 to 4 centimeters and in 32.5 per cent of those with lesions exceeding 4 centimeters.

The curability of carcinoma in regional nodes was found to be directly related to the pathological grade of the tumor the highest percentage of cures having been obtained in the group of patients having the lowest grade tumors. Table XI shows that 15.1 per cent of all cases with metastatic carcinoma in the lymph nodes were 5 year cures. This group included patients who had received palliative therapy only as well as many advanced secondary cases. When only the primary cases (all treatment at the Pondville Hospital) are considered the cure rate is 32.4 per cent or slightly more than double that for the entire series.

Only 40.7 per cent of the entire group of patients and 65 per cent of the primary group were considered to have operable metastases. The criteria for operability were not rigid and in some instances radical dissections were carried out in cases with only slight hope of cure. Table XII indicates that 50 per cent of the primary cases and 35.9 per cent of all cases with operable metastases attained 5 year cure status.

There were no well authenticated cures of cervical metastases by any method other than surgical eradication in this series, although one case was open to speculation. The patient had a lesion of the mid lower lip excised at another hospital this was followed by excision of a submental node at Pondville 10 months later at which time pathological examination

TABLE XIII.—NECK DISSECTIONS

Patients with Negative Lymph Nodes

	Cases	Died with disease or treatment failure—%	3 year cures—%	5 year cures—%
Unilateral dissection	55	5.7*	94.2	93.8
Bilateral dissection	25		100.0	100.0

*One postoperative death (sepsis)

Two died with uncontrolled primary disease

showed epidermoid carcinoma grade I Six months later three 2 millicurie gold radon seeds were implanted in a submaxillary lymph node in the right side of the neck although no biopsy was taken The patient died 9 years later of cardiorenal disease, apparently free of cancer

RESULTS OF NECK DISSECTION

One hundred and seventy-one dissections of the cervical lymph nodes were carried out in 126 patients with an operative mortality of 2 patients (1.6 per cent of the group) Analysis was based on 119 patients since 7 patients were reported dead of intercurrent disease in less than 3 years after operation and were therefore excluded as inconclusive.

Negative lymph nodes were reported by the pathologist for 80 patients who submitted to neck dissection Table XIII summarizes the results for these cases. The 3 cases listed as treatment failures included one operative fatality as the patient developed sepsis in the neck following a 'V' excision of the lip lesion and neck dissection done at the same time The 2 other cases were patients in whom the primary lesion was uncontrolled at the time of the neck dissection one of these had a lesion involving the commissure The fact that the only treatment failures in this group were patients with uncontrolled primary lesions emphasizes the importance of cure of the local tumor before an attempt is made to treat regional metastases.

In 39 cases metastatic carcinoma in the lymph nodes was present at the time of neck dissection A unilateral operation was carried out in 23 instances and 16 bilateral upper neck dissections were performed The cure rate for all patients who had neck dissection

TABLE XIV.—NECK DISSECTIONS

Patients with Proved Positive Nodes

	Cases	Died with disease or treatment failure—%	3 year cures—%	5 year cures—%
Unilateral dissection	23	78.0	26	26
Bilateral dissection	16	50	50	50
Total	39	64.3	35.0	35.9
Primary controlled	33	57.6	4.4	42.4

and proved metastases to the nodes was 35.9 per cent, as set forth in Table XII

It was felt that the low cure rate for unilateral dissections warranted further analysis Investigation revealed that 17 cases or 73.9 per cent of the group were listed as treatment failures for one of the following reasons Six of these patients developed recurrences in the primary tumor after unilateral neck dissection had been carried out indicating that the primary was not controlled at the time of the secondary procedure Three of these 6 had commissure lesions and 1 had extension of disease into the buccal mucosa Because of the local recurrence dissection of the other side of the neck was therefore not carried out in these cases and a seventh patient refused surgery to the second side It is obvious therefore that 6 of the treatment failures resulted from improper selection and that 1 patient refused completion of treatment. If one considers only those cases in which the primary disease was controlled before neck dissection was carried out, 42.4 per cent of the group are found to be 5 year cures

CONCLUSIONS

1 Carcinoma of the lip is the most readily curable malignant tumor of the oral cavity and treatment of 407 unselected cases at the Pondville Hospital resulted in 67.1 per cent 3 year cures Of the patients who received all their treatment at Pondville 81.4 per cent achieved 3 year cure status

2 Surgery is the preferred method of treatment at the Pondville Hospital

3 Three year cures are as significant statistically as 5 year cures in carcinoma of the lip

4 Carcinomas of the labial commissures are approximately twice as difficult to control as lesions in other locations on the lips.

5 Curability of carcinoma of the lip is directly related to the size and pathological grade of the primary tumor and the presence (or absence) of lymph node metastases.

6 It was found that 35.9 per cent of the patients who underwent neck dissection with pathologically proved cervical lymph node metastases attained the 3 year cure stage

BLOOD VOLUME AND OTHER DETERMINATIONS IN PREOPERATIVE AND POSTOPERATIVE CARE

Their Practical Applications in the Average Hospital

C ABBOTT BELING M D Med.Sc.D F.A.C.S., THOMAS V MORTON M D and
DONALD T BOSCH M D Newark, New Jersey

DETERMINATION of the amounts of circulating blood plasma, hemoglobin plasma proteins and body proteins in a patient and the manner in which these amounts reflect the patient's ability to recover from operative and other wounds have recently attracted interest. Other studies have been made of the depletion incident to weight loss and malnutrition associated with a multitude of conditions and of determining loss and replacement of protein blood and its fractions by reliable laboratory procedures.

Some of the earlier work was based on plasma protein percentage values determined by plasma specific gravity as disclosed by the falling drop method with associated estimation of hematocrit. It soon became apparent that specific gravity plasma protein percentage concentration and hematocrit values were not reliable indicators of the status of the total proteins in the circulating plasma or body tissues. The values for whole blood sodium chloride bore little relationship to the sodium chloride intake and urinary output and could be disastrously misleading as Collier pointed out in a paper on salt intolerance repudiating his previous formula for the administration of salt solutions postoperatively.

During studies (4) on the use of protein hydrolysate given orally we found that a more accurate approximation of the clinical status of severely ill patients could be obtained by correcting the plasma protein percentage value to conform with an ideal hematocrit of 45 per cent. The plasma protein percentage values in patients with severe burns which had been grafted with skin were misleading and sometimes remained the same though the

grafts began to shrink in size and the condition of the patient was obviously worse. The corrected values tended to parallel the status of the graft and usually rose when the grafts did well and became lower when the grafts shrank. This observation was made frequently.

In other instances however plasma protein percentage values, hematocrits, erythrocyte counts and whole blood sodium chloride values failed to portray what we thought was occurring in the patient. Other workers have made similar observations. How then might the patient's status be determined more accurately?

In 1932 Chang reported that the volume of blood in humans with nutritional deficiency was reduced. The same phenomenon was observed by Holman, Mahoney and Whipple in animals rendered hypoproteinemic. Abbott and Mellors and Lyons called attention to the fact that the circulating plasma proteins, circulating hemoglobin and cell mass might be greatly reduced while the plasma protein percentage concentration, hemoglobin and hematocrit were within normal limits. Recently Clark, Nelson, Lyons, Mayerson and DeCamp re-emphasized the weight loss reduction of blood volume and increase of interstitial fluid volume which occur in patients with malnutrition, carcinomas, long standing gastrointestinal disturbances and other conditions.

Reduction in circulating blood volume therefore would seem to be the more important aspect of the nutritional deficiencies accompanying various surgical and medical diseases. Any attempt to restore the blood volume to normal by introduction of simple fluids will result in dilution of the cell mass and the total circulating plasma proteins, the former producing more severe grades of ane-

From the Department of Surgery, Hospital of St. Barnabas, Newark, New Jersey.

mia and the latter reduction of the plasma protein concentration percentage. More profound degrees of anemia result in relative anoxia followed by passage of fluids into the interstitial spaces preventing restoration of the blood volume.

Actually then restoration of blood volume should depend on the introduction of adequate amounts of erythrocytes, protein and fluid with electrolytes. Restoration may be impeded unless sufficient amounts of erythrocytes and protein are given. This is not entirely true of the noncellular fluid component as it may be to varying degree brought in from the interstitial fluids.

Since ordinary laboratory determinations of hemoglobin concentration percentage, hematocrit and plasma protein concentration percentage do not indicate the true circulating erythrocyte mass and hemoglobin, circulating plasma volume and circulating plasma proteins, how may the surgeon in the average hospital obtain the pertinent information from the laboratory? What are the required procedures within the limits of practicability for the average laboratory not engaged in research? Three simple tests are required. These tests are determinations of the plasma volume and of the specific gravities of the plasma and whole blood.

DETERMINATION OF CIRCULATING PLASMA VOLUME

Of all the methods of determining circulating plasma volume the simplest is the one we employ adapted from that of Gregersen which consists essentially of the injection of Evans blue dye (T 1824) into the venous circulation and measuring the concentration of the dye in the plasma after 10 minutes. While some investigators weigh the syringe and the needle before and after injecting the dye it is not necessary for routine use and the error is not large enough materially to affect the results of their translation into effective therapy.

Equipment. In our method of determining circulating plasma volume the following equipment is used: (1) 4 Wintrobe tubes calibrated to 6 cubic centimeters containing 0.2 cubic centimeter of 1 per cent liquid heparin; (2) 2 five cubic centimeter ampules of Evans

blue (T 1824) dye; (3) 1 five cubic centimeter Luer Lok syringe with Luer Lok valve attached and 1 hypodermic needle; (4) 2 twenty cubic centimeter Luer Lok syringes; (5) at least 2 intravenous Luer Lok needles, No. 20 or No. 18 gauge with valves; (6) tourniquet; (7) watch with a second hand.

Technique at bedside. With a glass-marking pencil mark 2 of the Wintrobe tubes 'B' and 2 'A' to represent before and after injections of the dye. Set the two B tubes aside ready to receive blood. Take 1 ampule of Evans blue and make sure that all the solution is in the body of the ampule. Open the ampule in the usual manner with a file. Then take the 5 cubic centimeter syringe with valve and hypodermic needle and draw up the dye solution. The manufacturer has placed slightly more than 5 cubic centimeters in the ampule to allow for some loss in the needle and syringe barrel. If no dye has been left in the neck of the ampule usually about 5.3 cubic centimeters will come up in the syringe. Work out all air bubbles and adjust until 5.1 cubic centimeters remain in the syringe. The extra 0.1 cubic centimeter takes care of the loss of dye in the barrel of the syringe. Close the valve thus preventing any escape of the syringe contents, and remove the hypodermic needle. Place this syringe within easy reach for use following the next step. Apply the tourniquet for location of a vein only and remove it as soon as the vein is entered. Prolonged use of the tourniquet produces stasis resulting in serious error. The first 20 cubic centimeter syringe with intravenous needle is employed and blood is washed in and out of the syringe several times after making sure the tourniquet has been removed. Withdraw about 15 cubic centimeters of blood into the syringe, turn the shut-off valve, remove the syringe and introduce 6 cubic centimeters of blood into each B Wintrobe tube, cork each tube and invert to prevent clotting. Now take up the 5 cubic centimeter syringe with the dye and attach this unit to the needle and valve unit already in the vein. Open both valves, inject the dye rapidly and note the time of injection. Then rinse the syringe several times with blood, close one of the valves and withdraw the needle from the vein.

Now start looking for a suitable vein in the opposite arm so that it will be ready for the taking of the blood sample at the end of 10 minutes. Do not use a tourniquet during this time, although it may be used momentarily prior to entering the vein for taking the sample. Use the second 20 cubic centimeter syringe with valve and intravenous needle enter the vein just prior to 10 minutes quickly remove the tourniquet wash the syringe with blood several times withdraw 15 cubic centimeters, close the valve, and remove the needle. Disconnect the syringe and introduce 6 cubic centimeters of blood into each of the A Wintrobe tubes cork and invert. Take all the tubes B and A to the laboratory with the second ampule of Evans blue (T 1824).

Technique in laboratory A $\frac{1}{500}$ dilution of the other ampule of T 1824 dye is prepared by introducing 1 cubic centimeter of the dye with a 1 milliliter pipette into a 50 milliliter volumetric flask and filling it with water to the 50 milliliter line. $\frac{1}{2}$ cubic centimeter of this dilution is introduced into $4\frac{1}{2}$ cubic centimeters of plasma thereby making a final dilution of the dye of $\frac{1}{500}$, which is to be used in the colorimeter for comparison with the unknown.

Before centrifuging any of the blood determine the whole blood specific gravity from one of the B tubes by use of the copper sulfate method. The 4 Wintrobe tubes are then placed in the centrifuge and spun at 4,000 revolutions per minute for 15 minutes to give maximum packing of the cells. The hematocrit is determined and the plasma specific gravity is estimated by the copper sulfate method or the falling drop method of Barbour and Hamilton (2 3) if the equipment is customarily used.

The supernatant plasma of the B tubes is aspirated without disturbing the cells. Five cubic centimeters of the plasma is placed in a cuvette and read in a photoelectric colorimeter. This reading is the control value. Then remove $\frac{1}{2}$ cubic centimeter of the plasma from the cuvette and substitute $\frac{1}{2}$ cubic centimeter of the $\frac{1}{500}$ dilution of T 1824 dye. Mix thoroughly and read in the colorimeter. This reading is the known standard value.

In another cuvette place 5 cubic centimeters of the supernatant plasma from the A tube

and read in the colorimeter. This is the *unknown*. The colorimetric reading of the control (Cont) is subtracted from both the standard (Std) and the unknown (Un) before calculating the plasma volume according to the following formula

$$PI Vol = \frac{(Std - Cont) \times 2500}{(Un - Cont)}$$

After calculating the circulating plasma volume (PV) the total circulating blood volume is easily determined by the simple ratio $PV/BV = Hpl/100$ where PV represents plasma volume BV total blood volume and Hpl the percentage of plasma obtained by subtracting the hematocrit from 100. The circulating erythrocyte volume may be calculated if desired by subtracting the plasma volume from the total blood volume.

SPECIFIC GRAVITY OF PLASMA AND WHOLE BLOOD, HEMATOCRIT PLASMA PROTEINS HEMOGLOBIN

The specific gravity of plasma and of whole blood may be determined by several methods. Two are applicable to the average hospital laboratory. The first which we formerly used is the xylene bromo-benzene method of Barbour and Hamilton (2 3). It entails the use of a fairly large but portable piece of apparatus and requires some practice on the part of the technician. The method is simply mastered however and the calculations are not difficult. The specific gravity of the unknown may be read from the alignment chart which may be photographed and enlarged or purchased from a dealer in laboratory supplies from whom the entire apparatus may be obtained. We have found however that the copper sulfate method is simpler cheaper and requires less training and less time. The reader is referred to the work of Phillips Van Slyke *et al* (14) or the textbook on U S Army laboratory methods (17). Alignment charts are shown therein for calculating hemoglobin percentage plasma protein percentage and even the hematocrit from the whole blood and plasma specific gravities.

The method of Barbour and Hamilton is the more accurate but the apparatus is not universally obtainable. With the copper sulfate

method Edwards found that the results compare favorably with those obtained by photo-electric determination of hemoglobin.

There was also a good relation between the specific gravity of the plasma and Kjeldahl analyses for total proteins.

The method was found to be accurate to plus or minus 0.1 gram of protein per hundred cubic centimeters of plasma with not over 0.3 gram variation.

Hemoglobin percentage concentration and plasma protein percentage concentration are read directly from the appropriate alignment charts. The hemoglobin may be determined in the usual manner if desired. Those interested in the original formulation of the alignment between plasma specific gravity and the plasma protein content should refer to the work of Weech and his collaborators.

CALCULATED VALUES

Once all the available laboratory data have been presented to the surgeon he should determine the patient's weight for calculating the expected plasma and whole blood volumes, total hemoglobin and circulating plasma proteins, and by comparing with the corresponding amounts of each as determined from the laboratory data, discover the deficits. After multiplying the circulating plasma protein deficit in grams by 30 to take into account the loss of body protein (16) he will then have an estimate of the magnitude of the replacements of each component of the circulating blood and of body protein that will be necessary to make his patient a good operative risk.

All expected values are calculated from the patient's normal weight. In cases of extreme obesity, thinness or recent rapid gain of weight out of proportion to normal expectancy, it is better to use standard age, height and weight tables. These are readily available. The expected circulating blood volume, plasma volume and circulating hemoglobin mass are what we would normally expect if the patient were not ill. The corresponding determined values are what he actually has.

Expected total blood, plasma and cell volumes, expected total hemoglobin. These values may be calculated from weight, height and body surface area. Many investigations of correlation have been made by various workers. Row-

tree, Brown and Roth and Gibson and Evans concluded that blood volume bears a more constant relationship to body surface area than to weight, but the more recent work of Courtice with animals of such different surface areas as the rabbit, dog, goat and horse showed a close correlation with weight regardless of the area. Gregersen found similar close correlation with weight in humans. From these investigations it may be concluded that the following relationships exist between weight and circulating volumes:

$$\begin{aligned} \text{Expected total blood volume} &= \text{Kgm. (lbs.} \div 2.2) \\ &\times 85 \text{ expressed in c.c.} \\ \text{Expected total plasma volume} &= \text{Kgm. (lbs.} \div 2.2) \\ &\times 45 \text{ expressed in c.c.} \\ \text{Expected total cell volume} &= \text{Kgm. (lbs.} \div 2.2) \\ &\times 40 \text{ expressed in c.c.} \\ \text{Expected total gms. hemoglobin} &= \\ \text{blood volume} \times \text{hemoglobin (standard gms. \%)} & \\ 100 & \end{aligned}$$

Determined plasma, cell and blood volumes and hemoglobin. The plasma volume will have been determined according to the method described using Evans blue dye (T 1824). With this value all the others may be calculated using the formula $PV/BV = Hpl/100$. The total amount of circulating hemoglobin may be computed as follows:

$$\text{Total Hgb} = \frac{\text{Total bl. vol.} \times \text{Hgb (gms. \%)}}{100}$$

CALCULATION OF DEFICITS

The purpose of accumulating the data as outlined is to ascertain whether the patient's total blood volume, plasma volume, total circulating plasma proteins, total body protein, and hemoglobin deviate from normal and to what extent. When the deficits of the various components of the circulating blood have been calculated, proper steps may then be taken to correct them and lessen operative risk.

The data should be promptly recorded on a chart attached to the patient's record. These charts may be easily prepared by mimeographing. The headings should be placed in the left column and there should be 7 other columns across the sheet representing the 7 days of the week, similar to a temperature chart. The recommended headings are shown in the following example from our cases.

Weight kgm (lbs. + 2.2)	62.5
Plasma, sp gr	1.0240
Whole blood, sp gr	1.0550
Hematocrit (cells) per cent	43
Erythrocytes	4,790,000
Hemoglobin grams per cent	13.9
Plasma protein grams per cent	5.85
Plasma expect vol ($45 \times \text{kgm}$) c.c.	2,800
Determined vol c.c.	2,120
Deficit c.c.	680
Total blood vol. expect vol ($85 \times \text{kgm}$) c.c.	5,300
Determined vol c.c.	4,000
Deficit c.c.	1,300
Hemoglobin expect gm	866
Determined gm	656
Deficit gm	210
Proteins expect total ($P \times \text{Pl.P} + 100$) gm	196
Determined gm	124
Deficit gm	72
Body prot. deficit ($\times 30$) gm	2,160
Caloric requirement ($\text{kgm.} \times 25$) cal	1,562.5

CASE 1 St. B No 60346 From the foregoing data it is apparent that the patient, a male weighing 62.5 kilograms (137.5 lbs) had deficits of hemoglobin and circulating plasma proteins disclosed by a shrunken blood volume of 4,000 cubic centimeters as compared with an expected volume of 5,300 cubic centimeters. He gave a long history of malnutrition incident to a diverticulum of the stomach with ulceration. In order to prepare him properly for major surgery he was given 1,500 cubic centimeters of whole blood and supplementary feedings of protein hydrolysate whole protein and carbohydrate. During the 2 weeks prior to his first operation our nitrogen balance studies showed that he retained the nitrogen equivalent of more than 1,000 grams of protein which was about half of the estimated depletion of total body proteins. He withstood laparotomy well was in negative nitrogen balance for 3 days, and then remained in positive balance. During the next 18 days the feeding of about 125 to 150 grams of protein daily led to retention of the nitrogen equivalent of another 816 grams of protein. Transthoracic resection of the gastric cardia with the ulcer was performed. The patient received 1,500 cubic centimeters of whole blood, intravenous amino acids and glucose tube and oral feedings of protein hydrolysates whole protein and carbohydrate during the postoperative period. On one day only the fourth day after operation, when the caloric coverage was below 60 per cent of basic requirements there was a negative nitrogen balance.

Examining the data more closely it will be found that there was a deficit of 210 grams of hemoglobin. If 16.3 grams per cent is taken as normal for our laboratory approximately 1,290 cubic centimeters of whole blood should have been required to bring the total amount up to the expected value. Likewise it is found

that there was a deficit of 1,300 cubic centimeters of whole blood. Thus the 1,500 cubic centimeters of whole blood given in amounts of 500 cubic centimeters on consecutive days were sufficient. While the plasma in the whole blood was sufficient to add approximately the deficit of 72 grams of circulating protein the deficit of body protein was 2,160 grams. By massive protein and carbohydrate feedings maintaining a satisfactory caloric intake over half of the entire loss was made up in the immediate preoperative period of 2 weeks thus changing the operative risk from substandard to good.

Blood volume studies are particularly valuable in determining the specific component of the blood which needs replacement. When total hemoglobin and total plasma protein are determined and compared with the estimated normal a very accurate picture of the patient's specific need is obtained. This is exemplified by one of our patients who had been suffering from prolonged uterine bleeding. The following is abstracted from her records.

CASE 2 St. B No 63,55 Weight—61.4 kilograms (135 lbs) Total blood volume expected—5,355 c.c. determined—4,352 c.c. deficit—1,003 c.c. Total plasma volume expected—835 c.c. determined—326 c.c. excess—456 c.c. Total cell volume expected—2,520 c.c. determined—1,091 c.c. deficit—1,429 c.c. Hematocrit 25.2 per cent. Total plasma proteins expected—198.45 grams determined—186.53 grams deficit—11.92 grams. Hemoglobin 7.5 grams per cent. Total hemoglobin expected—803.25 grams determined—326.40 grams deficit—476.85 grams. These figures reveal a shrunken blood volume due primarily to a loss of red cell mass. The determined plasma volume was in excess of that which would be expected and the total plasma proteins showed a deficit of only 11.92 grams. There was, however, a total cell volume deficit of 1,429 cubic centimeters and a total hemoglobin deficit of 476.85 grams. The patient was in particular need of whole blood transfusions and iron.

The foregoing cases are illustrative of what can be done by utilizing the simple procedure as outlined calculating deficits and using indicated therapy. While we have carried out detailed nitrogen balance studies on many patients preoperatively and postoperatively and have gone into more detail regarding the caloric requirements and the relative merits of various forms of protein and protein deriva

tives such studies are for research purposes and are not expected of the average hospital. However the procedures as discussed herein are within the capacity of any hospital laboratory, are within the ability of average personnel, are not time consuming, are easily learned and performed and are reasonably accurate.

It has been said that unless basal caloric requirements are met, large losses of administered amino acids would occur in the urine. We have been surprised to find that positive nitrogen balance can be maintained in occasional patients receiving as little as 60 per cent of their basal requirements. This percentage probably represents about the lower limit. In our experience, an average level of at least 75 per cent of the basal calories should be provided even with intravenous amino acid administration.

DISCUSSION

Gradual lowering of mortality and widening of the scope of surgery have been mainly due to advances in anesthesia and in preoperative and postoperative care, other factors being about equal. Many studies have demonstrated the changes which may occur in the circulating body fluids as well as the tissues themselves in the presence of trauma or illness and have pointed the way to rational therapy. With any two series of similar cases the proper assessment of a patient's status and correction of deficits may make the difference between death or prolonged convalescence in one and rapid recovery in the other.

Determination of weight, plasma and whole blood specific gravity and plasma volume with the calculation therefrom of hematocrit, hemoglobin percentage, plasma protein percentage, expected plasma volume and deficit, expected and determined whole blood volume and deficit, expected and determined total hemoglobin and deficit, expected and determined total circulating plasma proteins and deficit, and caloric requirements are essential to proper preoperative care. Since but three easily performed laboratory tests are required in addition to the simple determination of a patient's weight, the necessary data should be obtainable in any hospital. The plasma volume technique is easily mastered with little

practice. The determination of plasma and whole blood specific gravity by the copper sulfate method may be rapidly done at the bedside in most cases by almost anyone after a few trials. Certainly the calculation of the remaining data by simple arithmetic should offer no serious difficulties. In fact, the collection of the information is easier than the persistent application of proper methods to correct such deficiencies as the data may disclose.

It may be argued that even these simple laboratory tests are not needed for intelligent care because whole blood and proteins may be given as the patient's clinical appearance seems to indicate. Emphatic exception must be taken to this attitude with the reminder that it is not uncommon to find serious deficits in persons who have not lost weight and who may appear to be reasonably good operative risks. Experience has taught us that while clinical impressions are often accurate they may be disastrously misleading and should not be relied upon solely.

The entire hemoglobin deficit should be corrected by transfusions of whole blood up to 1,000 cubic centimeters daily, signifying on 16.3 grams of hemoglobin per 100 cubic centimeters, or whatever other standard may be in use. There is little danger of overloading the vascular tree by quantitative replacement in the absence of certain cardiac disturbances, and rarely will the erythrocytes and hemoglobin percentage in the introduced blood attain the ideal normal values of 5,000,000 cells and 16.3 grams respectively. Lyons has previously reported that restoration to standard values for weight did not result in significant hemoconcentration or overloading. Operative blood loss should be made up quantitatively during operation and then no further transfusion may be necessary unless there is further loss in the postoperative period. The loss at operation will vary with different surgeons and types of cases. There is usually a tendency to underestimate not only the loss of cells but also of plasma which may escape in large quantities. While these facts are well known they are sometimes overlooked.

The plasma volume deficit may be overcome simultaneously with the administration of whole blood, plasma being a part of the

whole, unless the plasma loss has been disproportionately large. To such a case quantitative replacement is indicated.

The correction of protein deficits however is not as simple. As has been stated the total circulating plasma protein deficit must be multiplied by 30 to determine the total protein deficit of the body. Obviously it is impossible to replace the missing protein within a day or two. Often it may be impossible to make quantitative replacement in the preoperative period and complete restitution may not be necessary. In Case 1 retention of the nitrogen equivalent of more than 1,000 grams of protein within 2 weeks prior to operation was accomplished by giving about 125 grams of protein daily. When there is little time to prepare a patient for an emergency operation replacement of blood volume deficit with whole blood will carry him through satisfactorily. Approximately 35 to 40 grams of protein mainly albumin are introduced with every 1,000 cubic centimeters of whole blood. When there is ample time patients should be prepared by oral feeding of protein carbohydrates and fat in quantities sufficient to more than cover the caloric requirements.

We have had much experience during the past 8 years with almost all of the available products containing protein and protein hydrolysates with or without carbohydrates and have come to the conclusion that hydrolysates are rarely necessary during the usual preoperative period. We prefer to give whole proteins of high biological value, whenever possible, up to 150 grams daily, being certain to give an equal amount of carbohydrate and some fat. Suitable commercial preparations are available and if these are not desired, skim milk powder may be used in various ways. Much ingenuity may be necessary to persuade patients to take large amounts of protein and carbohydrates. Certain fundamentals must, however, be kept in mind. The proteins used must contain adequate quantities of the essential amino acids and should be supplemented with carbohydrate in about equal amount so that the proteins are not used in the body to manufacture carbohydrate. If any of the essential amino acids are lacking or if one or more should be

seriously deficient retention of the remainder is impaired and they appear in large quantities in the urine. This may also occur when insufficient calories are given. With the ingestion of 150 grams each of protein and carbohydrate with a fair amount of supplementary fat the caloric intake is usually adequate. It is in the immediate postoperative period that the caloric intake is the greater problem. The daily requirements of various vitamins are also important and should be covered with doses well above the basal level giving proportionately larger doses to those patients that have vitamin deficiencies.

After the patient has been thoroughly prepared for operation and blood and plasma lost at operation have been quantitatively replaced the immediate postoperative management confronts us. We urge early postoperative ambulation commencing within the first 24 hours and allow the average patient to choose his diet on the second day supplementing it with about 50 to 100 grams each of protein and dextrose daily until he is able to eat enough food to cover all the requirements. The latter usually occurs within a few days. The average case presents no serious problem. When surgery has been performed on the gastrointestinal tract with anastomoses, colostomies or obstructive resections the ingestion of large bulk is inadvisable. It is in this period that protein hydrolysates take their rightful place and are given intravenously through indwelling tube or orally. There are several available commercial solutions of protein hydrolysates for intravenous use. All of them according to our nitrogen balance studies are capable of maintaining positive balance. We strongly favor the use of those hydrolysate solutions which are combined with 5 per cent dextrose because it is possible to come closer to giving the necessary calories without unduly burdening the vascular tree. It is not our intention to evaluate the various intravenous solutions here. Any surgeon may easily determine for himself, from the commercial brochures the content of essential amino acids, dextrose and sodium chloride in each product.

The daily sodium chloride requirement averages about 6 grams but during the first 48

to 72 hours after operation may be too much. Salt intolerance during the immediate postoperative period is common and the sodium chloride content of intravenous and oral repletion should be known. When several thousand cubic centimeters of solution are administered daily the salt intake may be great. It is better therefore to refrain from giving any sodium chloride for at least 24 hours and thereafter the intake should be governed by the output. We recommend determining the plasma or whole blood sodium chloride which ever is customary in the given hospital before operation to learn if the concentration percentage is abnormally low so that restitution can be made. It is our practice to measure the daily urinary output to determine the sodium chloride concentration percentage on an aliquot portion, calculate the total daily salt output and provide quantitative replacement. The calculation of the daily output in operative cases is one of the more important tests and is strongly recommended.

While administration of intravenous fluid, amino acids and dextrose may be necessary following gastrointestinal resections and similar procedures, the associated feeding of hydrolysate or whole protein orally should be accomplished as soon as possible. For that purpose we use an Abbott Rawson tube with all gastric resections and start hourly feedings at once through the long lumen of the tube which reaches far into the jejunum. Dextrose and additional fluid requirements may be covered through the intravenous route. All obstructive resections of the colon and resections with end-to-end anastomosis are given hydrolysates and then whole protein by mouth. Our experience with such cases has been very gratifying and we have not encountered untoward distention or serious gastrointestinal reactions.

Finally it may be asked whether it is necessary to perform all the tests and calculations as outlined. The decision should be made on the clinical history and nature of the case. Probably they are unnecessary for normal healthy persons undergoing appendectomy, hernioplasty or procedures of lesser magnitude. Preparations for cholecystectomy and even repair of ventral hernias which some-

times are entered into lightly are not complete without thorough evaluation of the patient's condition. In our opinion the field of usefulness of the laboratory routine should be enlarged rather than narrowed. In this way the surgeon may do better for the patient and for himself.

SUMMARY

1. Many patients with a variety of diseases have shrunken total blood volume with deficits of plasma, hemoglobin and cells, circulating plasma proteins and body proteins.

2. The decreased blood volume with accompanying deficits may not be disclosed by the patient's weight and the usual laboratory estimations of hemoglobin, hematocrit and plasma proteins.

3. If the decreased blood volume and its associated deficits are not recognized there may be serious consequences for the patient during and after operation.

4. A simple routine is proposed which is practical for any small hospital and which may give accurate appraisal of a patient's status before operation. The routine consists of three simple procedures: determination of the specific gravity of plasma and whole blood and of the circulating plasma and whole blood volumes with the dye T 1824 (Evans blue). The technique of each is given in detail. From values determined and the weight of the patient all other data are calculated by simple arithmetic. Recording of the data systematically on a chart is recommended. Case examples are given.

5. From the data it is possible to estimate accurately a patient's need for one or more of the components of the circulating blood.

6. Application of the data to preoperative and postoperative care is discussed.

SURGICAL ASPECTS OF HYPERPARATHYROIDISM

Review of Sixty three Cases

B MARDEN BLACK, M.D. Rochester Minnesota

THE surgical problems associated with hyperparathyroidism broadly considered resolve themselves into the finding and removal of parathyroid tumors or the recognition and subtotal removal of hyperplastic tissue in cases of diffuse primary hyperplasia. The surgical difficulties have to do chiefly with the minuteness and varied locations of the parathyroid glands the small size of many of such tumors and the fact that the tumors may be multiple. Experience in the treatment of a sizable series of patients with hyperparathyroidism forms the basis for this report.

NATURE OF PRESENT SERIES

Many cases in the present series have been reported previously (5 6 11 21 29 32 37 38). Alexander Pemberton Kepler and Broders reviewed the first 14 cases in the series with particular reference to pathologic aspects and Keating and Cook reviewed the succeeding 24 cases with particular attention to diagnosis. The cases of diffuse primary hyperplasia have been reported by Rogers (30) and by Rogers and Keating (31). In the first case in the present series the condition in question was recognized in December 1928 (37) shortly after the first case of proved hyperparathyroidism in the United States had been reported by Barr Bulger and Dixon. From 1928 to 1942 the diagnosis was proved in 12 cases only. During 1942 a particular interest in the disease developed and in that year 4 new instances of it were recognized. In each succeeding year at least 10 instances of hyperparathyroidism have been proved. In 1946 fifteen new patients with this disease were treated. The remarkable improvement in the number of instances of hyperparathyroidism found has been due largely to a planned effort to make the diagnosis in cases of renal lithiasis.

From the Division of Surgery, Mayo Clinic.

Sixty three patients with proved hyperparathyroidism have been seen at the Mayo Clinic (through 1946). In 59 cases the diagnosis was proved at operation and in 4 it was verified at necropsy. In 4 cases (6.4 per cent) the disease was due to diffuse primary hyperplasia. In 2 of these the diagnosis was first made at necropsy and in the other 2 cases the patients were treated surgically. In 59 cases adenomas were found. In 1 case 2 adenomas were removed at the same operation. In each of 2 other cases, 1 adenoma was removed without influencing the hypercalcemia and hypophosphatemia so that probably a second adenoma existed in each case. If these 2 cases are acceptable as cases of multiple adenomas, then in 3 of the 59 cases of adenoma, the adenomas were multiple (5.1 per cent).

In addition to the 63 cases of proved hyperparathyroidism there were 7 other cases in which the clinical diagnosis of primary hyperparathyroidism seemed certain. In 6 of these 7 cases cervical and posterior superior mediastinal exploration only was carried out. In the seventh case cervical and anterior superior mediastinal exploration had been carried out before the patient was seen at the clinic and similar exploration was carried out here. Abnormal parathyroid tissue was not found in any of the 7 cases concerned. Six of the 7 patients have been considered as having undergone incomplete operations; the operation on the seventh has been considered as a surgical failure. Two of the remaining 6 patients were seen more than 15 years ago before the necessity of complete cervical and anterior superior mediastinal exploration was fully appreciated. One other patient died elsewhere 4 months after cervical exploration had been performed here with negative results. In the remaining 3 cases the importance of anterior superior mediastinal exploration was fully understood but for different reasons, was not carried out.

FACTOR OF SEX

Contrary to some reports (13, 27) but in keeping with others (21, 22), there was no great difference between the number of men and the number of women in the present series (31 women, 32 men). The explanation for this difference as it occurs in reported series is apparent when patients in the present series with osteitis fibrosa cystica and those without are considered separately. Among those with osteitis fibrosa cystica, women outnumbered men in the ratio of 32 to 1 whereas in the group without classical osseous disease men outnumbered women in the ratio of 25 to 1.

FACTOR OF AGE

The ages of the patients at the time treatment was carried out, varied from 14 to 68 years. Two patients were in the second decade, 10 were in the third, 18 were in the fourth, 15 were in the fifth, 14 were in the sixth and 4 were in the seventh.

DURATION OF SYMPTOMS

The duration of symptoms varied greatly. In 1 case symptoms due to recurrent renal stones had been present for 27 years; in another case the diagnosis was established within 1 week after the first attack of renal colic. The mean duration of symptoms among patients with osteitis fibrosa cystica but without renal complications was 4.16 years; among those with osteitis fibrosa cystica and renal complications it was 4.37 years. The mean duration of symptoms among patients with minimal or nondiagnostic lesions of bone and with renal complications was 10.12 years; the mean duration of symptoms among those with no disease of bone but with renal complications was 7.75 years.

DIAGNOSIS

Considering only cases of proved hyperparathyroidism in which the diagnosis was made during the life of the patient, about 20 per cent of the patients had generalized osteitis fibrosa cystica without renal complications. Somewhat less than 20 per cent had both renal complications and osteitis fibrosa cystica. Slightly more than 20 per cent had renal complications and some osteoporosis but not

osteitis fibrosa cystica. Approximately 35 per cent had complications of the urinary tract and no evidence of osseous disease. Generalized osteitis fibrosa cystica was present in less than 40 per cent of cases while nephrocalcinosis or urinary lithiasis was found in more than 70 per cent.

The importance of renal complications (2) is more clearly demonstrated if only these patients observed during the last 4 years of the study are considered. During this period 47 patients with proved hyperparathyroidism were seen; of these 47, forty-four received the diagnosis during life. Three patients without symptoms referable to either osseous or renal complications were seen during this time. Hence of this group of 47, there remained 41 patients with such symptoms. Osteitis fibrosa cystica was present in 27 per cent of these 41 patients and renal diseases were found in 88 per cent.

The 3 patients who did not have symptoms (6.8 per cent of the patients for whom the diagnosis was made during life in the past 4 years) are of particular interest since the diagnosis was established only because determinations of the content of calcium in the blood were carried out. In 2 of these 3 cases such determinations were done because of convulsions and in 1 case they were made because of postmenopausal osteoporosis. It is thus evident that although renal or osseous complications usually are present and serve to suggest the diagnosis, the disease may exist and be diagnosed in the complete absence of complications. Indeed in every case the diagnosis depends ultimately on the characteristic changes in values for calcium and phosphorus. If the adult patient¹ has not been receiving large amounts of vitamin D which produces changes in the values for calcium and phosphorus indistinguishable from those associated with hyperparathyroidism, the demonstration of hypercalcemia, hypophosphatemia, hypercalciuria and hyperphosphaturia will establish the diagnosis with complete certainty. (1) These characteristic findings may be

¹Albright (2) has pointed out that children have an unstable calcium equilibrium and that osseous atrophy of disease, in children, may be associated with hypercalcemia, hypercalciuria and even with renal stones. The youngest patient in the present series was 14 years of age at the time the diagnosis was established.

modified in cases of chronic renal disease with retention of metabolites in that retention of phosphorus may occur with consequent depression of the level of calcium in the blood. Since the diagnosis can be made with such certainty it follows that cervical exploration never should be advised in an effort to establish the diagnosis and that the surgeon must accept the fact that an adenoma or primary hyperplasia exists in every case and be prepared to prolong the dissection until such abnormal parathyroid tissue is found.

PATHOLOGIC ASPECTS

Comprehensive reviews of the pathologic aspects of parathyroid tumors have been prepared by Castleman and Mallory, Alexander and associates, Norris (26) and others (3, 16) further extended discussion is beyond the scope of this review. Controversy still exists as to whether the usual so-called adenoma should be considered benign or malignant. In the present series no tumor either recurred locally or metastasized¹ in spite of the fact that local excision rather than radical resection was carried out. Hyperfunctioning malignant tumors which have both metastasized and recurred after local excision have been reported (18, 23, 24) however and the cytologic characteristics of such tumors have been so similar to those of tumors in the cases in our series that many on cytologic grounds, have been considered as malignant (5). To simplify discussion and since the same treatment was carried out regardless of the impression of the pathologist as to whether the tumor was benign or malignant the term adenoma has been used throughout the review. The term is used however without implications as to whether the adenoma was considered benign or malignant on cytologic grounds.

In the 4 cases of diffuse primary hyperplasia in the series, the hyperplasia was entirely typical (3). In the 2 cases in which surgical treatment was carried out pseudopodia which have figured prominently in descriptions of the gross appearance of primary hyperplasia

were not present although larger masses of hyperplastic tissue were lobulated and contained cystic and hemorrhagic areas (Figs. 1 and 2).

NORMAL PARATHYROID GLANDS

Recognition Although it is difficult to recognize normal parathyroid glands grossly there is agreement (8, 14, 15, 36) that after the surgeon has had practice he can recognize normal parathyroid glands grossly with considerable certainty. Some knowledge of the variation in size, number, color and location of the glands is imperative for the surgeon who proposes to operate because of disease of these glands.

Weight, size and number A normal parathyroid gland weighs 30 to 40 milligrams and measures 6 to 7 millimeters by 3 to 4 millimeters by 1.5 to 2 millimeters (19, 20, 28, 36). The largest parathyroid gland in Welsh's (36) series measured 15 by 6 by 3 millimeters and the heaviest gland weighed 100 milligrams. Large parathyroid glands approach the size of parathyroid tumors particularly if the two parathyroid glands on the same side of the neck are fused. The number of parathyroid glands varies from 2 to 6 or even more. Gilmour and Martin (20) in a study of the parathyroid glands of 527 persons who came to necropsy found 4 glands in approximately 80 per cent, more than 4 glands in 6 per cent and fewer than 4 glands in 14 per cent. When 5 or 6 glands were found the supernumerary glands were small and were situated in the immediate vicinity of one of the normal glands. When only 2 or 3 glands were found their small total weight suggested that other parathyroid glands had not been found in the dissection. Experience at operation would tend to support the implications of the study of Gilmour and Martin (20) that 4 glands are present in the great majority of cases, and that when fewer than 4 glands are found it is more probable that glands have been missed in the dissection than that they are absent.

Form The normal parathyroid gland is so soft that its shape is usually determined by surrounding structures but when the gland is situated in loose areolar tissue it assumes an oval form. The surface is smooth but has a

¹One instance of carcinoma of parathyroid origin with hyperparathyroidism, local recurrence, and regional metastasis has been observed at the Mayo Clinic since 1916. Report of this case appeared in the *Proceedings of the Staff Meetings of the Mayo Clinic*, 1924, 3: 8-14.

characteristic finely granular appearance caused by a network of minute vessels beneath a thin capsule. The vessels enter at a fairly definite hilus. Small adenomas retain most of the physical characteristics of the normal gland. Larger adenomas are more likely to be molded flattened, or otherwise distorted by surrounding structures and those which weigh more than 2 or 3 grams generally assume an oval or globular form and demonstrate surface molding only.

Color The color of the normal gland varies according to the fat content. Before puberty the gland is composed of chief cells (12) and has a characteristic coffee-brown color. Fat cells which dilute the brown color with varying admixtures of yellow appear at puberty and increase progressively until the person attains the age of about 40 years. During middle age the fat tissue remains fairly constant. It does not increase with old age (12). The fat cells may be concentrated toward one extremity of the gland sometimes giving the appearance of a partial halo. The gland frequently is enclosed within a small pad of fat (19, 36) and is evident only as a somewhat darker center within the fatty pad. Fat cells are absent in adenomatous tissue so that the color is darker brown than that of the usual adult gland. Small hemorrhagic and cystic portions often are found in both adenomas and in the enlarged glands of primary hyperplasia.

Location The aberrant location of many parathyroid glands is dependent in part on the migration of their anlagen during the embryologic period (15, 25, 35) and in part on the displacement of the adult gland particularly an enlarged gland caudally by both gravity and negative intrathoracic pressure (15, 33). The region in which a given gland may be found is predictable (14, 15, 33) and this fact constitutes the anatomic basis for the surgery of hyperparathyroidism. The superior parathyroid gland develops in close association with the lateral anlage of the thyroid gland (Fig. 3a) and migration during the developmental stage is not great. On the basis of embryologic migration the gland should lie between the upper pole of the larynx and the lower pole of the thyroid gland in the space bounded anteriorly by the deep layer of the

middle cervical fascia and posteriorly by the prevertebral fascia. The gland is situated well posteriorly and lies on the pharynx or esophagus rather than on the thyroid gland (36). The usual position of the gland is not near the superior pole of the thyroid gland but at about the junction of the middle and upper thirds of the lobe. The superior gland lies in a plane dorsal to the recurrent laryngeal nerve and inferior thyroid artery (36). Although this gland is found more easily than the inferior gland because of its limited embryologic migration its posterior and medial position in relation to the thyroid gland is well worthy of emphasis.

The inferior parathyroid gland develops embryologically in close association with the thymus gland (Fig. 3b). The anlage originates from the pharyngeal wall rostral to that of the superior gland and migrates caudally along with the thymus lateral to the developing superior parathyroid and thyroid glands. It may be carried so to speak completely into the anterior superior part of the mediastinum with the developing thymus (10) but usually its descent stops near the inferior pole of the thyroid gland. The inferior gland lies in a more ventral plane than the superior and usually is situated anterior to the recurrent laryngeal nerve and the inferior thyroid artery. In the adult person on a developmental basis the inferior parathyroid gland may be found in the visceral compartment of the cervical fascia at any level theoretically from the upper border of the larynx to well into the anterior superior or even into the anterior mediastinum. The more usual positions of the inferior gland are (1) associated with the posterolateral surface and inferior poles of the thyroid gland near the branches of the inferior thyroid artery but anterior to these arteries and (2) more medially usually in relationship to the inferior thyroid veins. In the latter case the inferior parathyroid gland may be some distance caudad to the thyroid gland.

In addition to being subject to variations in position dependent on embryologic development adult parathyroid glands particularly when enlarged may be displaced caudally by the same forces that cause low lying adenomas of the thyroid gland to become intrathoracic.

If the gland is situated well posteriorly the displacement is toward or into the posterior superior mediastinum and if it is situated more anteriorly it may be displaced toward or into the anterior superior mediastinum. Because of the dorsal position of the superior parathyroid gland the displacement in the adult person is toward or into the posterior superior mediastinum. An inferior gland may be displaced either into the anterior superior or posterior superior mediastinum depending on its position before displacement (33).

Parathyroid glands occasionally are present on the anterior surface of the thyroid gland (34). Whether parathyroid glands are ever actually situated within the thyroid gland is still controversial. Welsh reported that he had never found parathyroid tissue continuous with thyroid tissue. Norris (25) found that in embryos developing thyroid tissue occasionally partially encircled a developing parathyroid gland but never completely surrounded it. Cope (15) reported that a parathyroid gland had not been found within the thyroid gland at the Massachusetts General Hospital. In the present series neither normal glands nor parathyroid adenomas were found within the thyroid gland. Conversely there have been occasional reports (17) of intrathyroid parathyroid adenomas. Gilmour (19) in a series of 428 necropsies found that very rarely parathyroid glands and thyroid gland tissue were fused without intervening connective tissue and added that in 2 cases a parathyroid gland was found well within the thyroid gland.

Vascular pedicles. A parathyroid gland in its more usual location receives its blood supply from the superior or inferior thyroid artery or from the anastomotic artery which courses along the posterior surface of the thyroid lobe. When the gland develops in the mediastinum it may receive its blood supply from any neighboring artery. Parathyroid glands which develop in the cervical region and are subsequently displaced into the mediastinum remain attached to the arterial system of the thyroid gland so that the displaced gland may be found by tracing the vascular pedicle downward. As a rule the pedicle originates close to the thyroid gland. All parathyroid glands

in the posterior superior part of the mediastinum have pedicles while those in the anterior superior mediastinum may or may not have pedicles (Fig 4).

PARATHYROID ADENOMAS

Situation. Adenomas may develop in any parathyroid gland wherever situated and enlarged glands in or near the superior strait of the thorax are likely to be displaced caudally. This tendency as well as the erroneous conception that the superior parathyroid gland is situated near the superior pole of the thyroid gland probably accounts for the fact that the majority of parathyroid adenomas have been thought to develop in the inferior parathyroid glands (27). Of the adenomas removed surgically in the present series 26 were on the left 27 were on the right 1 was in the midline and in 4 cases the location was not indicated in the operative note. The ratio of involved inferior to superior glands was approximately 3 to 2. It was evident however early in the review that adenomas found near the inferior pole of the thyroid gland usually were considered as having developed in the inferior parathyroid gland and often the gland was considered to have been an inferior gland on no other basis.

Mediastinal adenomas.—The reported incidence of mediastinal adenomas varies considerably and probably depends to a large extent on individual definition of a mediastinal adenoma. More than 80 per cent of the adenomas in Norris' (27) collected series were in the region of the inferior glandule—that is, near or inferior to the inferior poles of the thyroid gland. Since the average size of the tumors in this series was 3.2 by 2.1 by 1.7 centimeters it is evident that many of the tumors must have extended into the superior part of the mediastinum. Norris reported however that in only 19 of the 281 cases (6.8 per cent) were the tumors mediastinal. In a series of 49 adenomas reported by Cope 9 were situated in the mediastinum 5 in the anterior superior and 4 in the posterior superior.

In the present series the classification of adenomas as cervical or mediastinal seemed so uncertain that the attempt was abandoned. However no estimate of the

Fig 1 Diffuse primary hyperplasia. The total weight of hyperplastic tissue was 52.5 grams. The small cystic and hemorrhagic portions are clearly shown.

Fig 2 Diffuse primary hyperplasia. The large water-clear cells are well shown. All parathyroid tissue showed the same change. Hematoxylin and eosin $\times 110$.

number of adenomas which could not be found by dissection under direct vision through the cervical approach was attempted. In 1 of the 57 cases in which adenomas were removed surgically, 2 adenomas were found making a total of 58 adenomas. In 2 cases after cervical and posterior superior mediastinal dissection, a single parathyroid adenoma was removed without influencing the disease. Presumably in both cases, a second adenoma was present and presuming further, it was situated in the mediastinum. In 3 cases adenomas which were not apparent on cervical exploration were removed from the anterior superior mediastinum. In 2 of these the anterior superior mediastinum was explored after the sternum had been split, in the third case a vascular pedicle leading into the mediastinum from the right inferior thyroid artery permitted sufficient dissection under direct vision for exposure and removal of the adenoma through the cervical approach (Fig 4). In addition to the 57 cases of proved tumors (58 adenomas), there were 6 cases in which clinical diagnosis had been regarded as certain but in which results of cervical dissection were negative. If it can be assumed that these 6 patients had mediastinal adenomas, then of 64 adenomas (58 proved adenomas plus 6 hypothetical adenomas) 11 (17 per cent) were situated in the anterior superior part of the mediastinum and could not be removed under direct vision during the cervical exploration and posterior

superior mediastinal exploration. Such an incidence probably is too high since the assumption that an adenoma not found on cervical exploration is located in the mediastinum is not tenable.

Size. The adenomas in the present series varied in weight from less than 100 milligrams to 101 grams (Figs 5, 6 and 7). In 17 per cent of cases the adenomas weighed less than 500 milligrams; in 25 per cent they weighed 1 gram or less; in almost 50 per cent they weighed 2.5 grams or less. In slightly more than 25 per cent of cases the adenoma weighed more than 5 grams. Small tumors obviously are more difficult to find surgically than are large tumors. In practice tumors which weigh more than 1 gram are recognized easily. Those materially smaller not only may be difficult to recognize but they may be well hidden within sulci of the thyroid gland or by other cervical or mediastinal structures, since small tumors tend to be caught within crevices, whereas larger tumors tend to be displaced into regions occupied by loose areolar tissue.

Some conception of the expected size of the tumor would be of considerable aid prior to operation. Castleman and Mallory were of the opinion that some correlation existed between the intensity of the disease as judged by the changes in values for calcium and phosphorus in the blood and the size of the tumor. Cope (15) proposed subsequently that this correlation could be used to determine whether

If the gland is situated well posteriorly the displacement is toward or into the posterior superior mediastinum and if it is situated more anteriorly it may be displaced toward or into the anterior superior mediastinum. Because of the dorsal position of the superior parathyroid gland the displacement in the adult person is toward or into the posterior superior mediastinum. An inferior gland may be displaced either into the anterior superior or posterior superior mediastinum depending on its position before displacement (33).

Parathyroid glands occasionally are present on the anterior surface of the thyroid gland (34). Whether parathyroid glands are ever actually situated within the thyroid gland is still controversial. Welsh reported that he had never found parathyroid tissue continuous with thyroid tissue. Norris (25) found that in embryos developing thyroid tissue occasionally partially encircled a developing parathyroid gland but never completely surrounded it. Cope (15) reported that a parathyroid gland had not been found within the thyroid gland at the Massachusetts General Hospital. In the present series neither normal glands nor parathyroid adenomas were found within the thyroid gland. Conversely there have been occasional reports (17) of intrathyroid parathyroid adenomas. Gilmour (19) in a series of 428 necropsies found that very rarely parathyroid glands and thyroid gland tissue were fused without intervening connective tissue and added that in 2 cases a parathyroid gland was found well within the thyroid gland.

Vascular pedicles. A parathyroid gland in its more usual location receives its blood supply from the superior or inferior thyroid artery or from the anastomotic artery which courses along the posterior surface of the thyroid lobe. When the gland develops in the mediastinum it may receive its blood supply from any neighboring artery. Parathyroid glands which develop in the cervical region and are subsequently displaced into the mediastinum remain attached to the arterial system of the thyroid gland so that the displaced gland may be found by tracing the vascular pedicle downward. As a rule the pedicle originates close to the thyroid gland. All parathyroid glands

in the posterior superior part of the mediastinum have pedicles while those in the anterior superior mediastinum may or may not have pedicles (Fig. 4).

PARATHYROID ADENOMAS

Situation. Adenomas may develop in any parathyroid gland wherever situated, and enlarged glands in or near the superior strait of the thorax are likely to be displaced caudally. This tendency as well as the erroneous conception that the superior parathyroid gland is situated near the superior pole of the thyroid gland probably accounts for the fact that the majority of parathyroid adenomas have been thought to develop in the inferior parathyroid glands (27). Of the adenomas removed surgically in the present series 26 were on the left, 27 were on the right, 1 was in the midline and in 4 cases the location was not indicated in the operative note. The ratio of involved inferior to superior glands was approximately 3 to 2. It was evident, however early in the review, that adenomas found near the inferior pole of the thyroid gland usually were considered as having developed in the inferior parathyroid gland and often the gland was considered to have been an inferior gland on no other basis.

Mediastinal adenomas.—The reported incidence of mediastinal adenomas varies considerably and probably depends to a large extent on individual definition of a mediastinal adenoma. More than 80 per cent of the adenomas in Norris (27) collected series were "in the region of the inferior glandule—that is, near or inferior to the inferior poles of the thyroid gland." Since the average size of the tumors in this series was 3.2 by 2.1 by 1.7 centimeters it is evident that many of the tumors must have extended into the superior part of the mediastinum. Norris reported however that in only 19 of the 281 cases (6.8 per cent) were the tumors mediastinal. In a series of 49 adenomas reported by Cope, 9 were situated in the mediastinum, 5 in the anterior superior and 4 in the posterior superior.

In the present series the classification of adenomas as cervical or "mediastinal" seemed so uncertain that the attempt was abandoned. However an estimate of the

number of adenomas which could not be found by dissection under direct vision through the cervical approach was attempted. In 1 of the 57 cases in which adenomas were removed surgically, 2 adenomas were found making a total of 58 adenomas. In 2 cases after cervical and posterior superior mediastinal dissection a single parathyroid adenoma was removed without influencing the disease. Presumably in both cases a second adenoma was present and presuming further it was situated in the mediastinum. In 3 cases adenomas which were not apparent on cervical exploration were removed from the anterior superior mediastinum. In 2 of these the anterior superior mediastinum was explored after the sternum had been split. In the third case a vascular pedicle leading into the mediastinum from the right inferior thyroid artery permitted sufficient dissection under direct vision for exposure and removal of the adenoma through the cervical approach (Fig 4). In addition to the 57 cases of proved tumors (58 adenomas) there were 6 cases in which clinical diagnosis had been regarded as certain but in which results of cervical dissection were negative. If it can be assumed that these 6 patients had mediastinal adenomas then of 64 adenomas (58 proved adenomas plus 6 hypothetical adenomas) 11 (17 per cent) were situated in the anterior superior part of the mediastinum and could not be removed under direct vision during the cervical exploration and posterior

superior mediastinal exploration. Such an incidence probably is too high since the assumption that an adenoma not found on cervical exploration is located in the mediastinum is not tenable.

Size. The adenomas in the present series varied in weight from less than 100 milligrams to 101 grams (Figs. 5, 6 and 7). In 17 per cent of cases the adenomas weighed less than 1 milligram; in 25 per cent they weighed 1 gram or less; in almost 50 per cent they weighed 2.5 grams or less. In slightly more than 25 per cent of cases the adenoma weighed more than 5 grams. Small tumors obviously are more difficult to find surgically than are large tumors. In practice tumors which weigh more than 1 gram are recognized easily. Those materially smaller not only may be difficult to recognize but they may be well hidden within sulci of the thyroid gland or by other cervical or mediastinal structures, since small tumors tend to be caught within crevices, whereas larger tumors tend to be displaced into regions occupied by loose areolar tissue.

Some conception of the expected size of a tumor would be of considerable aid in operation. Castleman and Mallory were of the opinion that some correlation existed between the intensity of the disease and the changes in values for calcium and phosphorus in the blood, and the Cope (15) proposed a correlation could be u

Fig. 3. Wax plate reconstruction of the thyroid, thymus and parathyroid gland and associated structures in the 4.5 millimeter embryo. The developmental relationship between the parathyroid gland (parathyroid 4) and parathyroid gland (parathyroid 5) is shown. The adult inferior parathyroid gland originates rostral to the adult superior parathyroid gland and in the descent it passes lateral and anterior to the adult superior gland. In plaster reconstruction of the thyroid, thymus and parathyroid glands in the 3 millimeter embryo, the glands in this stage occupy approximately the same position as in postnatal life. The explanation for the usual position of the adult inferior parathyroid gland both lateral and anterior to the adult superior gland is evident from the reconstruction. The in-

timat variation of the inferior parathyroid gland with the thymus gland is well illustrated. (Reproduced, with permission of the publisher from W. D. C. L.: Development of the thyroid, parathyroid and thymus glands in man. *C. C. Morgan Foundation of Washington Publication No. 443. Contribution to Embryology*, 933, 24, 93-99.)

or a second adenoma was present in a given case after one adenoma had been found. This correlation was studied in cases in the present series and although there were frequent exceptions there was some tendency for smaller tumors to be associated with lower values for calcium and larger tumors to accompany higher values for calcium. The correlation was more marked in the case of smaller tumors than larger tumors. The variation in size of adenomas associated with a given value of calcium in the blood was so great however that the presence of a second adenoma could not be postulated after the identification of one adenoma (Fig. 8). No correlation was found between duration of symptoms and size of the tumor or between the age of the patient and size of the tumor. Osteitis fibrosa cystica was associated with larger tumors more often than were renal complications although the correlation between values for calcium in the blood and size of the tumor was closer than that between osseous disease and size of the tumor.

TREATMENT

The necessity for meticulous dissection and the avoidance of blood stained tissues has long

Fig. 4. An adenoma of the parathyroid gland displaced into the superior mediastinum. The vascular pedicle connecting it to the thyroid arterial system is well shown, especially in the inset. Not all adenomas in the superior superior mediastinum have vascular pedicles originating in the cervical region.

Fig. 5.

Fig. 6 A parathyroid adenoma weight 3.5 grams. The patient had classical osteitis fibrosa cystica and nephrocalcinosis. The value for calcium in the blood fell from 18.7 milligrams per 100 cubic centimeters before the operation to 6.75 milligrams 18 days after the operation.

Fig. 7.

Fig. 6.

Fig. 7 A parathyroid adenoma associated with vascular pedicle showing pyriform shape weight 3.3 grams. The patient had recurrent nephrolithiasis and associated osseous disease. The value for calcium in the blood was 13.5 milligrams per 100 cubic centimeters before operation. It was 8.7 milligrams per 100 cubic centimeters after operation had been carried out.

been emphasized (14, 15) furthermore the surgeon must have developed the ability to recognize normal parathyroid glands. Immediate microscopic inspection of tissue by means of frozen sections should be available for the interpretation of specimens taken for biopsy and to aid in the recognition of diffuse primary hyperplasia. Biopsy should be employed sparingly and specimens for biopsy should be taken carefully because of the concomitant danger of destruction of a normal parathyroid gland. Adequate anesthesia for prolonged and extensive dissection in the neck must be provided. At the Mayo Clinic local anesthesia produced by 0.5 per cent procaine hydrochloride, augmented by nitrous oxide and oxygen is used invariably because of the possibility of injury to the recurrent laryngeal nerves. The aim of the operation is the methodical identification of each parathyroid gland and the golden opportunity for such identification is at the first operation. The recognition of normal parathyroid glands may be virtually impossible at secondary operations and normal glands in secondary procedures may be destroyed during the dissection which is far more difficult technically than at the primary operation. Nothing is gained by the removal of normal parathyroid glands in cases of hyperparathyroidism (14) if an

adenoma subsequently is found and removed chronic tetany will follow if all normal parathyroid tissue has been sacrificed. Because of the possibility of malignancy adenomas invariably should be removed completely (5). In cases of diffuse primary hyperplasia subtotal excision of the hyperplastic tissue should be carried out with the preservation of between 30 and 200 milligrams of hyperplastic

Fig. 8 The relationship of the value for blood calcium to the weight of the parathyroid gland. For instance 85 per cent of the patients with parathyroid adenomas weighing up to 2.5 grams had blood calcium values of 14 milligrams per 100 cubic centimeters or less, whereas among those with parathyroid tumors weighing more than 2.6 grams, only 37 per cent had so low a value for blood calcium.

tissue¹ (3-4) Care should be taken to guard the blood supply of the remnant.

I am in accord with the view of Cope (15) that exploration of the anterior superior mediastinum should not be done at the same time as the cervical and posterior superior mediastinal exploration. It should be done only after the cervical incision has healed and after the clinical course and chemical findings in the blood have demonstrated that the patient has not been cured. Complete cervical and posterior superior mediastinal dissection is a prolonged operation and with the knowledge that the entire operation is to be confined to these two regions dissection is likely to be more thorough than it would be if complete mediastinal dissection were carried out at the same operation. Blind blunt dissection of the anterior superior mediastinum through the cervical incision is to be condemned. It is not only dangerous but adenomas may be so soft that they cannot be recognized by palpation alone; they may be situated so far within the thorax that they cannot be reached finally the scarring and hemorrhage resulting from blunt dissection will make subsequent exploration under direct vision of the anterior superior and anterior parts of the mediastinum more difficult and less certain. The posterior superior mediastinum is readily explored under direct vision through the cervical approach. Since the only way that parathyroid adenomas attain the posterior superior portion of the mediastinum is by displacement from the cervical region there invariably is a vascular pedicle arising from the arterial system of the thyroid gland.

The sequence of steps in cervical dissection is of little consequence as long as some systematic plan is followed. Cope (15) has suggested that since the superior parathyroid glands are comparatively easily found the two superior glands possibly should be identified first whereas Norris (27) has pointed out that since more than 80 per cent of reported adenomas have been situated near the inferior

poles of the thyroid gland this area should be exposed first.

As a rule I carry out fairly complete dissection on the first side before crossing the midline. The same incision used for thyroidec-tomy is employed and after extensive mobilization and rotation of the lobe of the thyroid, the usual position of the superior parathyroid gland is explored. After gross identification of the superior parathyroid gland or after a reasonable search has failed to reveal it, dissection is continued distally around the inferior pole of the thyroid gland and toward the mediastinum. The areolar and fatty tissue around the inferior thyroid veins is carefully stripped from the veins. After the inferior gland has been identified grossly or after the area has been sufficiently dissected to demonstrate that the gland is not present in its more usual location the integrity of the recurrent laryngeal nerve is determined and similar dissection is carried out in the opposite side of the neck. Removal of specimens for biopsy and of parathyroid tissue should be postponed until this much of the bilateral dissection has been completed.

If then a tumor has not yet been found, dissection is extended as indicated by the missing parathyroid glands. For example if a superior parathyroid gland has been found, no further dissection need be carried out above the level of this gland. Conversely if a superior parathyroid gland has not been found this side of the neck must be explored from the upper border of the larynx to the inferior pole of the thyroid gland including the area anterior and medial to the superior pole behind the superior pole between the thyroid gland and esophagus or pharynx between the trachea and esophagus behind the esophagus and laterally around the carotid artery. If the inferior gland has not been identified the area of the dissection is extended as far as possible under direct vision into the anterior superior mediastinum and posteriorly well into the posterior superior mediastinum. If an adenoma still is not found dissection is similarly extended on the opposite side of the neck. The inferior thyroid artery and its larger branches as well as the anastomotic vessel between the inferior and superior thyroid arter-

¹McKee and I (1) review 11 reported cases of primary hyperparathyroidism with particular reference to the amount of tissue saved. Although reports are few persistent hyperparathyroidism as not observed when less than 200 milligrams, estimated weight, of tissue had been preserved and tetany as not observed when more than 30 milligrams, estimated weight, had been preserved.

ies will have been well cleared of areolar tissue on both sides by this stage of the dissection and vascular pedicles leading inferiorly should be evident if present. Such pedicles must not be divided during the dissection since they may lead to an adenoma in either the anterior superior or posterior superior mediastinum. If such a pedicle is present it usually is possible to follow it by dissection under direct vision, and to find and remove the adenoma since such adenomas are not displaced deeply into the mediastinum (Fig. 4).

Finally, if the adenoma still has not been found partial removal of one lobe or both lobes of the thyroid gland may be done particularly if the lobe is enlarged or nodular. The chance, however, of the finding of an intrathyroid parathyroid adenoma excluding parathyroid adenomas deep in a sulcus of the thyroid gland is remote.

At the conclusion of a fruitless, complete cervical exploration the surgeon should know which parathyroid gland is missing not only so that the side of the mediastinum in which the tumor is more likely to be found will be indicated, but also so that a check on the thoroughness of the cervical exploration will be provided. Unfortunately this ideal may not be achieved but even so, the principle is sound and adherence to it should encourage complete cervical dissection. In the usual case an adenoma will be found during the course of the cervical and posterior superior mediastinal dissection. In such a case, it is still necessary to carry out a reasonably complete bilateral cervical and posterior superior mediastinal dissection in order that other adenomas may be excluded.

Mediastinal exploration. As I have said exploration of the anterior superior part of the mediastinum should be delayed until the cervical incision has healed and until it can be demonstrated that the patient has not been cured. The exploration should be carried out through a sternum splitting approach of adequate size to afford exposure. Tumors lying within the thymus gland and within the plane of the great veins have been reported (15) if a tumor is not found during the dissection of the areolar tissue in the mediastinum thymectomy is indicated.

POSTOPERATIVE TETANY

Postoperative tetany in cases of hyperparathyroidism is better understood and less feared than formerly. Mild transient tetany may develop 3 or 4 days after operation because of either temporary hypoparathyroidism thought to be due to hypofunction of the remaining normal parathyroid glands or because of the sudden shift of the content of calcium and phosphorus in the blood. In the latter case symptoms of tetany may be present when values for calcium in the blood are higher than normal. Such tetany usually requires no treatment. In cases of advanced osseous disease particularly those in which values for alkaline phosphatase are higher than 20 Bodansky units per 100 cubic centimeters of serum severe tetany may develop. Albright (1) has postulated that in such cases the bones take up calcium and phosphorous ions so rapidly that serious depletion of these ions develops in the circulating blood. In such cases massive doses of calcium and vitamin D or dihydrotachysterol may be required. Permanent tetany results if all functioning parathyroid tissue has been removed or destroyed during the dissection. Permanent tetany requires continuous treatment with calcium and dihydrotachysterol.

In the present series of 57 patients who were cured surgically 30 did not have postoperative tetany whereas tetany of some degree developed in 27. In 2 patients in the latter group the tetany became permanent. The tetany of 15 patients was considered mild while in the remaining 10 patients severe symptoms developed. Symptoms of severe tetany were observed only in patients who had osteitis fibrosa cystica; conversely symptoms of severe tetany were not seen unless classical osseous disease was present.

SUMMARY

Sixty-three patients with proved hyperparathyroidism were observed at the Mayo Clinic through 1946. The disease was due to a single adenoma in 56 cases, to multiple adenomas in 3 cases and to diffuse primary hyperplasia in 4 cases. The ages of the patients ranged from the second to the seventh decade. Complications of the urinary tract were more common

and more important than osseous complications. The diagnosis was established with certainty in 3 cases in the absence of any complications on the basis of the characteristic changes in the content of calcium and phosphorus in the blood and urine. Since the diagnosis can be made with complete certainty, exploration of the parathyroid glands is never indicated to establish the diagnosis, and the surgeon must accept the fact that in every case of hyperparathyroidism one adenoma or more or primary hyperplasia is present.

The treatment of hyperparathyroidism is surgical. Adenomas should be removed completely and in cases of diffuse primary hyperplasia the hyperplastic tissue should be excised subtotally with the preservation of between 30 and 200 milligrams of hyperplastic tissue. In more than 80 per cent of cases the abnormal tissue may be found by dissection under direct vision through a cervical incision (cervical and posterior superior mediastinal dissection). A second operation through a sternotomy incision will be necessary in the remaining cases (anterior superior mediastinal dissection). Secondary dissection is more difficult and far less certain than primary dissection so that every effort should be made at complete operation both in identifying the parathyroid glands present and in designating those missing at the first cervical dissection.

INTERATRIAL SEPTAL DEFECT—ITS EXPERIMENTAL PRODUCTION UNDER DIRECT VISION WITHOUT INTERRUPTION OF THE CIRCULATION

ALFRED BLALOCK M.D. F.A.C.S. and C. ROLLINS HANLON M.D., Baltimore Maryland

THERE is at present no well recognized technique for the production of interatrial septal defect although in a number of clinical conditions the establishment of such a defect might act to balance the right and left sides of the heart and thereby benefit the patient. In personal communications both Blakemore and Swan have mentioned this possibility. An analogous view has been expressed by Levine in commenting on the remarkable manner in which mitral stenosis and arterial hypertension may be tolerated when present in the same patient. Levine suggests an explanation based on equalization of the burdens on the right and left sides of the heart. Expressed in the form of a lay parable he says 'if one is to have a soft or flat tire on a motor car it would be of advantage to have the one on the other side in a similar condition'. It is known that patients with mitral stenosis and interatrial septal defect (the so called Lutembacher syndrome) may survive for remarkably long periods. In such instances according to White the deficiency of the interatrial septum has been credited with lightening the burden imposed on the pulmonary circulation and right ventricle by the mitral stenosis.

A number of methods may be used to produce interatrial septal defects. With the venae cavae occluded temporarily, one may approach the septum through a slit in the right auricle to produce the interatrial communication by incision with a knife by excision of a segment with scissors or with the electrosurgical unit or by simple punching with an instrument such as a hemostat.

None of these techniques provides the advantage of direct vision and there is moderate

loss of blood despite attempts at hemostasis by temporary complete obstruction of both venae cavae. Such occlusion of the cavae is poorly tolerated and the operation must be completed promptly to avoid cardiac arrest. Defects so produced are usually of a size which cannot be determined with accuracy at the time of operation and their persistence is highly problematical. We have been led by these considerations to develop a technique which permits the leisurely production of large interatrial defects under direct vision without undue loss of blood and obstruction to blood flow through the cavae or auricles.

METHOD

Adult mongrel dogs were used varying in weight from 6 to 20 kilograms. Anesthesia was induced by drop ether followed by introduction of an endotracheal catheter with an inflatable cuff. A mechanical device provided regular periodic inflation of the lungs with ether vapor while the chest was open. The chest was entered through the right fourth intercostal space. Silk was employed as suture material throughout.

An important factor in the procedure is a special occlusive clamp described in a previous publication (2). This clamp (Fig. 1) consists of two semicircular jaws of rounded wire the upper one sliding in a grooved handle and capable of exerting pressure against the lower fixed jaw by means of a spring. A modified form of this clamp which approximates by screw action has been used successfully; the holding power is greater but there is increased danger of crushing the auricular wall.

TECHNIQUE OF PRODUCING AN INTERATRIAL SEPTAL DEFECT

The method is based on the anatomical fact that the right superior pulmonary veins are

Fig. Clamp for occluding segment of blood vessel while allowing blood flow in its remaining portion. A spring in the handle maintains the jaws in contact.

closely adherent to the dorsal wall of the right auricle which forms one component of the interatrial septum. The ventral wall of these veins merges imperceptibly into that portion of the left auricular wall forming the interatrial septum. It is therefore indeterminate at what point the adherent walls of the pulmonary veins and right auricle may properly be said to become the interatrial septum; nevertheless it is possible by excision of the adherent walls

Fig. Relations between the two auricles and the pulmonary veins. (Compare 11th diagram in Fig. 4.)

of the right auricle and the pulmonary veins, to make a communication between the two sides of the heart. This principle is illustrated in the accompanying diagram (Fig. 2).

The pulmonary veins from the apical and cardiac lobes of the right lung are isolated over a 15 millimeter area between the parenchyma of the lung and their point of passage dorsal to the right auricle (Fig. 3). The pericardium is incised along its attachment to the pulmonary veins and reflected to the left, exposing the ventral aspect of the right auricle. The arterial supply to the lobes is occluded during the procedure by bulldog clamps or more conveniently by traction on braided silk ligatures passed around the vessels. With the pulmonary veins occluded distally by traction on braided silk ligatures, the spring clamp is applied so that the fixed jaw lies dorsal to the pulmonary veins and the movable jaw lies ventral to the right auricle (Fig. 4). On closure the clamp includes the ventral wall of the right auricle, the interatrial septum, and the dorsal wall of the superior pulmonary veins at their point of entry into the left auricle. These relations are shown in Figure 5b. The right inferior pulmonary veins and all the left pulmonary veins empty freely into the

Fig. 3. The pericardium is being reflected to expose the ventral aspect of the right auricle.

Fig. 4. Pericardium opened, clamp in place and incision in ventral surface of the pulmonary vein. (Compare with diagram in Fig. 2)

left auricle, nor is there any interference with inflow from either vena cava.

It is apparent that with an incision in the pulmonary vein and in the right auricle one has rendered visible within the clamp both intimal surfaces of the interatrial septum (Fig. 5a). By exerting traction on this isolated septum one may remove with scissors up to 2 centimeters of its most lateral portion still maintaining a bloodless field within the jaws of the clamp. Occasionally the cut edge of the septum will retract medially between the jaws

of the clamp but this serves only to establish the interatrial communication before removal of the clamp. It does not result in bleeding because the ventral wall of the right auricle is still approximated to the dorsal intimal surface of the pulmonary veins. The free lateral edge of the right auricle is then fixed to the distal ventral wall of the pulmonary veins by a running mattress suture of No. 00000 braided silk on an atraumatic needle (Fig. 6). Additional sutures are rarely required. The entire suture line is superficial since the dorsal half of the

pulmonary veins is intact. The pericardium is closed by a few sutures of fine silk covering the site of the anastomosis.

RESULTS

The operation as described was performed on 31 dogs. One animal died during operation because the clamp had been improperly applied and obstructed the vena cava. One died of distemper 9 days after operation and another of widespread pleural and pericardial infection after 6 days. In both of these latter dogs the defects were found at autopsy to be fully patent.

Fig. 7. Interatrial septal defect viewed from within right auricle 63 days after operation. Note the left auricle with its entering pulmonary veins.

Of the remaining 28 dogs 5 are alive and in good condition from 4 to 7 months after operation. Twenty three dogs were killed under anesthesia from 10 to 114 days after operation. In 16 of these there were large smoothly healed defects without evidence of scarring or constriction. A typical result is seen in the accompanying photograph taken approximately 2 months after operation (Fig. 7). The defect measures 20 by 13 millimeters and

Fig. 8. Free edge of remaining interatrial septum showing smoothly covered muscle 20 days after operation. $\times 64$. R, Endocardium of right auricle, L, endocardium of left auricle; S, scar.

through it one can see the openings of the pulmonary veins. Of the remaining 7 dogs 2 showed marked constriction of the defect and in 5 there was complete occlusion of the opening. None of the dogs showed any symptoms attributable to the septal defect although in those surviving for long periods there was some cardiac enlargement.

It is difficult to assign exact causes for the failures reported but undue trauma to the suture in early experiments and the excision of very small segments of the septum in some instances undoubtedly led to most of the poor results. When it was realized that large defects were well tolerated the more radical excision was used and produced better results.

Healing of the free edge of the remaining interatrial septum was usually smooth and there was little tendency for closure of the defect by hyperplastic scarring or by adherence to surrounding tissues. The type of healing may be seen in Figure 8.

SUMMARY

A technique has been described by the use of which one may produce interatrial septal de-

fects under direct vision without interruption of the circulation with minimal loss of blood with fairly accurate control of size and with good prospect of maintained patency. The results have been considered to be satisfactory in 16 of the 23 animals which were examined at autopsy from 10 to 114 days subsequent to operation.

The possible use of interatrial septal defects as a therapeutic measure has been commented on briefly in a previous communication dealing with complete transposition of the pulmonary artery and aorta. Possible applications of this method for balancing the work of the two sides of the heart under certain abnormal conditions await further investigations.

STUDIES ON VAGOTOMY IN THE TREATMENT OF PEPTIC ULCER

III Physiological Aspect

LESTER J. MILES, M.D. and KARI A. MEYER, M.D., F.A.C.S., Chicago, Illinois

THE history of vagotomy and its use in the treatment of peptic ulcer have been recently reviewed (31, 32). It is likely that all of the procedures used in man by the early workers in this field resulted in only partial vagus section. Dragstedt's introduction of complete vagotomy as a treatment for peptic ulcer in 1943 (7) has caused renewed interest in the subject.

In June of 1946 a study of vagotomy in the treatment of peptic ulcer was started on one of the surgical services at the Cook County Hospital (K. A. M.). During the following year vagus section was carried out in 35 instances of peptic ulcer in which surgery was indicated. A report on the use of ulin in testing for completeness of vagotomy (12) and a clinical evaluation of the study (21) are published elsewhere. The present report is concerned primarily with the changes in gastric function following vagotomy.

Studies on the effect of vagotomy on gastric function in man have been previously reported. A decrease in the volume and acidity of the night secretion and a decrease in gastric motility following vagotomy have been constant findings. Dragstedt (6) and Thurston (34, 35) state that vagotomy has no effect on the secretory response of the stomach to histamine and caffeine. Moore (22, 23) states that the secretory response to histamine is unchanged following vagotomy. Crimmon (11) and Smithwick report that some patients have a decreased gastric response to histamine following vagotomy.

TESTS

Physiological studies of the stomach were made before and after vagotomy in 30 patients.

From the Medical Institute for Medical Research of the Cook County Hospital and from the Department of Surgery of the Cook County, Duquesne and North Western University Medical Schools, Chicago.

Dr. Miles is Abbott Fellow in Surgery, North Western University Medical School.

Each of the following determinations was made on a significant number of patients before and after surgery: (1) 12 hour night secretion; (2) basal secretion; (3) the effect of histamine on gastric secretion; (4) the effect of caffeine on gastric secretion; (5) the effect of atropine on basal secretion; (6) the spontaneous motility of the stomach and the effect of ulin on secretion and motility; (7) the pain threshold to electrical stimulation; and (8) the production of pain by the introduction of acid into the stomach. The method employed and the results will be discussed for each test. The secretory studies reported were conducted on patients in whom the ulcer was duodenal in location. There is a different group of patients for each study although considerable overlap exists.

1 Twelve Hour Night Secretion

Method. The patients were fed a standard soft diet at 4:30 p.m. and allowed nothing by mouth thereafter. At 7:30 p.m. a Levine tube was passed into the stomach and the stomach was emptied. Continuous suction was maintained from 8 p.m. until 8 a.m. when the 12 hour specimen of gastric juice was collected for acid determination (20, 28, 37).

Results. The results are summarized in Table I. Before surgery the average night secretion of 70 determinations in 22 patients was 47.4 milliequivalents per 12 hours with a range of 0 to 154.0 milliequivalents per 12 hours. After complete vagotomy and gastrectomy the average night secretion of 48 determinations in 14 patients was 1.5 milliequivalents per 12 hours with a range of 0 to 11.8 milliequivalents per 12 hours, a decrease of 97 per cent from the preoperative value.

After complete vagotomy without gastrectomy the average night secretion of 13 determinations in 4 patients was 3.0 milli-

Fig 1 Average basal secretion before and after vagotomy (16 hours previous fasting)

Fig 2 The effect of histamine on gastric acidity before and after vagotomy (average of 11 patients)

equivalents per 12 hours with a range of 0 to 12.3 milliequivalents per 12 hours.

After incomplete vagotomy the average night secretion of 10 determinations in 3 patients was 12.7 milliequivalents per 12 hours with a range of 3.2 to 48.5 milliequivalents per 12 hours.

2 Basal Secretion

Method The determination of basal secretion (2-17) was usually preceded by a night secretion study. When not preceded by a night secretion study, complete aspiration of the gastric residuum was performed at the beginning of the test. In all instances when the basal se-

Fig. 3. The effect of afferent vagal activity before and after vagotomy (stage of 12 patient)

Fig. 4. The effect of trypsin on gastric acidity (stage of 1 patient)

cretion study was started at 8 a.m. the patient had not eaten since 4:30 p.m. the previous day and usually the Levine tube had been in place all night. The stomach was kept empty by means of continuous syringe aspiration and

the specimen of gastric secretion collected at 15 minute intervals for titration. The acid response during the period of basal secretion was used as a control for the subsequent secretory study. Basal secretion was deter-

Fig. 5. Preoperative insula test. Motility tracing showing spontaneous and insulin induced hunger contractions.

mined for 1 hour before a stimulant or depressant drug was administered. If however there was a marked spontaneous rise or fall in the basal secretion the control period was continued until a fairly constant rate of secretion was reached.

Results. Before vagus section, the average basal secretion of 56 determinations in 22 patients was 3.7 milliequivalents per hour (Fig. 1). The average of 14 determinations in 4 patients following incomplete vagotomy was 2.3 milliequivalents per hour. The average of 41 determinations in 18 patients following complete vagotomy was 0.2 milliequivalents per hour, a decrease of 95 per cent from the preoperative value.

3 The Effect of Histamine

Method. Following a period of at least 1 hour of basal secretion an intramuscular injection of 10 milligram of histamine phosphate was given. Aspiration of the stomach was

continued as during the basal period and the sample titrated at 15 minute intervals.

Results. Figure 2 is a composite curve demonstrating the secretory response of the stomach to histamine before and after complete vagotomy. The average secretory response in 11 patients was 12.7 milliequivalents per hour before surgery and 3.6 milliequivalents after complete vagotomy.

TABLE I — TWELVE HOUR NIGHT SECRETION BEFORE AND AFTER VAGOTOMY

	Free acid milliequivalents		Number of determinations	Number of patients
	mean	range		
Before operation	47.4	0-54	70	2
After operation Complete vagotomy with gastroenterostomy	5	0-8	38	14
Complete vagotomy without gastroenterostomy	3.0	0-18.3	13	4
Incomplete vagotomy	8.7	3.2-48.5		3

Fig 6 Postoperative insulin test. Motility tracing showing no spontaneous or insulin induced hunger contractions following complete vagotomy.

decrease of 72 per cent. In all 11 cases of complete vagotomy a decreased secretory response to histamine was noted, and in 2 an achlorhydria was present.

4 The Effect of Caffeine

Method. The method employed was that of Roth, Ivy and Atkinson. After the determination of basal secretion 0.5 gram of caffeine with sodium benzoate in 200 cubic centimeters of water was given through the Levine tube. Aspiration of the gastric contents was resumed $\frac{1}{2}$ hour later and continued for 2 hours unless the secretory rate had returned to or below the basal level at the end of $1\frac{1}{2}$ hours.

Results. Figure 3 is a composite curve demonstrating the secretory response of the stomach to caffeine before and after complete vagotomy. The average secretory response in 12 patients was 7.2 milliequivalents per hour

before surgery and 1.0 milliequivalent per hour after complete vagotomy, a decrease of 86 per cent. In all 12 cases of complete vagotomy a decreased secretory response to caffeine was noted, and in 3 an anacidity was present.

Before vagotomy 7 patients showed an ulcer type response to caffeine. Following complete vagotomy 4 of these had no response to caffeine, 1 a normal curve. Before surgery 4 patients had a normal response. After complete vagotomy 3 of these had an ulcer type curve although only a slight response, and 1 had no response.

5 The Effect of Atropine on Basal Secretion

Method. After the basal secretion had been determined, an intramuscular injection of 1.2 milligrams of atropine sulfate was given and the effect on basal secretion noted (14, 16, 20).

Results. Before vagotomy the free acid was reduced to zero following the injection of

Fig. 7 The effect of insulin on gastric acidity before and after vagotomy

atropine in 7 of 11 cases (Fig 4) Following complete vagotomy the basal secretion of free acid was usually zero thus the effect of atropine could not be ascertained

6 The Spontaneous Motility of the Stomach and the Effect of Insulin on Gastric Secretion and Motility

Method After the determination of the night secretion at 8 a.m., a second Levine tube with a rubber balloon attached was passed into the stomach. The balloon capacity was about 200 cubic centimeters but in order to avoid mechanical stimulation only 10 to 50 cubic centimeters of air were used in the balloon during the test. The balloon was placed in the cardiac end of the stomach and its position confirmed by inflation and gentle withdrawal of the attached tube until there was a slight tug as the balloon reached the cardiac sphincter of the stomach. By this means it was assured that the balloon was not in the pylorus where it may cause mechanical stimulation. The balloon was then only partially inflated and connected to a water manometer. Continuous recordings of gastric motility were made on a slowly moving kymograph.

A control period was then observed for at least 1 hour of basal secretion and motility the gastric secretions being aspirated through the

first tube as in the preceding tests. Then 14 to 16 units of regular insulin were injected intravenously and the effect on gastric motility and acidity noted for 1½ to 2 hours.

A review of the literature and detailed discussion of this subject have been previously reported (32)

Results Before vagotomy the motor response to insulin hypoglycemia was determined in 27 patients. All of these patients showed spontaneous Type I and occasional Type II and III hunger contractions (Fig 5). Following the insulin injection there was an immediate suppression of hunger contractions lasting ½ to 1¼ hours and usually followed by a period of hypermotility. At the height of the hypoglycemic reaction there was a sudden marked increase in the free acid. The average preoperative secretory response in 22 comparable patients with duodenal ulcer is shown in Figure 7.

Following surgery 3 patients had a marked acid response to insulin hypoglycemia (Fig 7) and are therefore classified as cases of incomplete vagotomy. These patients also had either spontaneous or insulin induced hunger contractions postoperatively.

The remainder of the patients had no acid response to insulin hypoglycemia and are considered to be cases of complete vagotomy.

These patients had no spontaneous hunger contractions in the fundus of the stomach after 16 to 22 hours of fasting and no hunger contractions following insulin hypoglycemia (Fig 6)

The ravenous hunger often produced by insulin hypoglycemia is present following complete vagotomy (13)

In 9 cases an attempt was made to determine gastric tone before and after complete vagus section. One to 100 cubic centimeters of air were placed in the balloon and the intra gastric pressure recorded from the manometer in centimeters of water. A series of readings was taken before and after vagotomy. The results were equivocal.

7 *The Pain Threshold to Electrical Stimulation*

Method The procedure of Boyden and Rigler was used. A wire was threaded into a Rehfuess tube and attached to the metal olive. This served as the active electrode when placed in the stomach. An indifferent electrode was placed on the back or thigh. The electrodes were attached to a Harvard inductorium supplied by two dry cell batteries.

Results The minimum current necessary to produce sensation in the region of the stomach was noted in 7 patients before and after vagotomy. The results were equivocal.

8 *The Production of Pain by the Introduction of Acid into the Stomach*

Method The procedure of Palmer was used. 200 cubic centimeters of 0.5 per cent hydrochloric acid was instilled into the stomach by means of a Levine tube. If no pain was produced the test was repeated in 1/2 hour.

Results In 3 of 7 patients in whom tests were made the acid produced typical ulcer pain before surgery. In 1 of these pain was produced after complete vagotomy. This was in a patient with marginal ulcer. On the first and second postoperative day no pain was produced. On the third day x ray examination revealed that the Levine tube had passed through the gastroenterostomy. The tube was pulled back into the stomach and the acid test repeated with the production of ulcer pain within 5 minutes. The other patients in whom

tests were made had duodenal ulcers, moderate to severe pyloric obstruction and delayed gastric emptying. At surgery both a vagotomy and gastroenterostomy were performed. It is questionable whether the acid reached the ulcer after operation.

DISCUSSION

The secretory activity of the stomach may be divided into the period of interdigestive or continuous secretion and the digestive period of secretion. The latter consists of three phases: the cephalic, the gastric, and the intestinal (1, 15, 29).

Gastric secretion during the interdigestive period may be due to either humoral or nervous factors or to both. Dragstedt has stressed the possibility that the hypersecretion of duodenal ulcer is due to constant excessive activity of the gastric secretory fibers in the vagus nerves (8). The marked diminution of the night secretion and basal secretion following complete vagotomy indicates that the vagus is the most important factor contributing to gastric secretion during the interdigestive period. The secretion of acid during this period is not abolished by complete vagotomy; thus the vagus is not the only factor concerned. In addition, the lowering of night secretion and basal secretion may be due to a decreased responsiveness to circulating stimuli.

The cephalic phase of gastric secretion is mediated entirely by the vagi. The gastric phase of secretion can be provoked by mechanical stimulation and secretagogues, and has been considered independent of the vagus. In view of the marked decrease in the secretory response to histamine and caffeine following complete vagotomy, it is apparent that the gastric phase of secretion is to some extent influenced by the vagus.

A synergistic action of histamine and cholinergic drugs has been demonstrated (9, 24). Grossman has suggested that the responsiveness of the gastric glands to all types of stimuli may be dependent upon the basal level of acetylcholine production in the stomach (12). This would explain the decreased action of secretagogues following complete vagotomy.

It should be stressed that in our studies, the secretory response to chemical stimuli was

reduced in every patient in whom the insulin test indicated that vagotomy was complete. After incomplete vagotomy with gastroenterostomy the response was often slightly decreased. After incomplete vagotomy without gastroenterostomy the secretory response to chemical stimuli was essentially unchanged being sometimes slightly decreased and occasionally somewhat greater than the preoperative value. We feel that it is probable that the inconsistent results reported by other workers may be due to failure to distinguish between completely and incompletely vagotomized subjects. The excellent correlation which we have found to exist between a negative post operative response to insulin (indicating complete vagotomy) and depression of the secretory response to histamine and caffeine constitutes strong confirmatory evidence of the reliability of the insulin test when properly performed as an indication of the completeness of vagotomy.

The fact that complete vagotomy is followed by immediate relief of ulcer symptoms and apparent healing of the ulcer does not prove that excessive vagal activity is the cause of peptic ulcer. Both periods and all phases of gastric secretion are either partially or completely dependent upon vagus function. Complete vagotomy interrupts a mechanism necessary for chronicity of peptic ulceration although this mechanism may not be primarily disturbed.

Eight patients were tested 3 to 9 months after vagotomy. In 7 of these there was no evidence of return of gastric function to the preoperative level. One patient showed a return of vagus function after 9 months as demonstrated by the insulin test. The response in this case to the other tests was similar to the immediate postoperative values. Vanzant reported in the dog a return of gastric acidity to near normal 2 years following vagotomy. The late effects of complete vagotomy on the gastric secretory and motor function in man are not yet certain.

The determination of basal secretion is an excellent method for the study of the interdigestive period of gastric secretion. It is easier to determine the basal secretion than the night secretion and the results are equally accurate.

In addition the basal secretion serves as a control for the study of the action of stimulants or depressants on gastric secretion.

CONCLUSIONS

Following complete vagotomy there is a marked reduction of the night secretion and the basal secretion. The secretory response of the stomach to caffeine and histamine is greatly reduced.

Insulin hypoglycemia produces an increase in gastric secretion and usually motility. This action is abolished by complete vagotomy. There are no spontaneous hunger contractions in the fundus of the stomach up to 9 months following complete vagotomy.

The vagi are the sole mediator of the cephalic phase of gastric secretion. They are the most important factor concerned in the interdigestive period and a contributing factor in the gastric phase of secretion. Complete vagus section in some manner interrupts a mechanism necessary for chronicity of peptic ulceration.

CERVICAL CYTOLOGY KEY TO DIAGNOSIS OF EARLY UTERINE CANCER

HARRY O'ORN M D Montreal Canada

Of all the research work which is being done in gynecology in general and in cancer of the female genital tract in particular there is little of such great importance or of such paramount value to the practicing physician as that work which is directed toward the study of the cells of the female genital organs. While the applications of this technique are many and varied its most important function at the present time is concerned with the early diagnosis of pelvic malignant neoplastic activity. By the study of the cells contained in the secretions of the genital tract of the woman an accurate indication of the growth activity of her organs can be obtained. The use of the vaginal and cervical cytology tests in the diagnosis of cancer of the pelvic organs has now been extended to every doctor who can use a speculum and has the facilities provided by the government mails. It is now possible by the use of a specific technique to mail slides to specialized cytology centers where they are quickly stained read and the report sent out by way of the most rapid route.

A few words concerning the basic principles of this method may be in order at this point (1). Most of the genital epithelium in the female arises from the muellerian ducts and it possesses the characteristic property of the muellerian tissue namely that of desquamation. This means that the surface cells are slowly cast off and pass down through the tubes corpus of the uterus, and cervix and finally come to rest in the vaginal pool where they are mixed with the secretions of the vagina itself. Thus we find in the vaginal pool a conglomeration of cells from all parts of the female genital apparatus. Shields Warren quotes Dale Rex Coman who found that cells of carcinoma of the cervix could be separated

with less than one-sixth of the force required to separate normal epithelial cells of the cervix. This being the case not only is cancer of the uterus an exfoliative lesion but the desquamation from these growths proceeds at a much faster rate than that from normal tissue. Cells detached from the surface of the tumor fall into the lumina of the uterus and vagina, where they become mixed with the desquamated cells of the normal epithelium (11). The process is a kind of natural curettage going on without interruption and always providing fresh and easily obtainable material for study.

If the above mentioned properties of the normal and malignant genital epithelium really exist then the cancer cells should be identifiable in the vaginal secretions. That this is the case was proved conclusively by Papanicolaou and papers covering this phase of his work were published in 1928 (12) 1933 (13) 1943 (16) etc. This work was corroborated by Ayre in Montreal and by Meigs and Graham working in Boston. Papanicolaou's original technique (17) consists in drawing the secretions from the posterior fornix of the vagina into a pipette fitted with a rubber suction bulb. This secretion is then transferred to a clean glass slide where it is spread evenly. The slide is then placed into an ether alcohol mixture for fixation. After they are stained by a specialized method, mounted and dried the slides are ready for examination.

During the course of his manifold investigations Ayre found that smears taken directly from the os of the cervix were a more efficient means of diagnosis than those taken from the vagina (1, 2). The reasons for this are logical and easy to understand. The majority of genital malignant conditions arise from the uterus either the fundus or the cervix. There is at the cervical os a variable amount of thick sticky mucus. Therefore a greater con-

From the Gynecology Laboratory, Department of Obstetrics and Gynecology, Royal Victoria Hospital, and McGill University.

centration of malignant cells will be found in this mucus than will be present in the vaginal pool. The cancer cells are in this way picked up before they are diluted by the not inconsiderable vaginal fluid. A second significant advantage of the cervical as opposed to the vaginal smear lies in the fact that the cells are aspirated directly from the squamocolumnar junction of the cervix the precise area where epidermoid carcinoma of the cervix has its origin. In this way not only the late full blown cases of cancer are found but the early lesions which were being missed previously may now be detected while they are still in a curable stage.

Some workers (9) agree that in some instances the cervical smear may be of greater value than the vaginal smear. They believe that such situations are few in number and believe that in the cervical method one of the greatest assets of the vaginal technique is lost namely its simplicity. The cervical method requires the insertion of a speculum into the vagina before the smear can be taken something which is not done when the older vaginal technique is employed. This then is the reason for the belief that the vaginal cytology smear is to be preferred to the cervical one. The validity of this line of reasoning is open to serious doubt and question. We admit that the taking of the cervical smear involves the use of a slightly more detailed technique but doubt that this is of any significance whatever. We are not interested at this point to stress the advantages of the cervical method from a cytological standpoint. Our reasons for preferring this technique are much more fundamental in character. To any physician who practices gynecology either as a specialty or as a part of general practice the insertion of a speculum should not constitute a problem. It is an extremely simple procedure which takes no longer than a couple of minutes, a small price to pay in order that the cervix may be subjected to careful scrutiny. Many articles are being written today about the delayed diagnosis of cancer of the cervix. Much blame is heaped on the members of our profession who treat abnormal vaginal bleeding and other female complaints without first doing a pelvic exami-

nation. I think we all agree that this is a pernicious practice which must be abolished. What competent gynecologist would dare dismiss a possible cancer case from his office before he had done a complete pelvic examination? And what woman may not be harboring an unsuspected cancer in her uterus? The cytology test is a wonderful diagnostic aid, but we must never allow ourselves to lean so heavily on a laboratory test that we neglect the clinical side of the picture. Hence we fail to see the logic in the belief that the cervical cytology test is inferior because it necessitates the use of a speculum with subsequent visualization of the cervix. Rather this is a distinct advantage. If the cervical cytology test never accomplishes anything more than getting all practitioners to perform pelvic examinations (digital and visual) on each and every one of their female patients, then it will still have been responsible for a great forward step in the fight for early diagnosis of uterine cancer.

The simplicity of the technique of taking the cytology smears is truly remarkable. The procedure must however be carefully and painstakingly carried out with full attention being given to detail. If this is not done the slides will be of inferior quality and the diagnosis will be more difficult to make. A very short summary follows.

The smear from the external os is taken with the aid of a bivalve vaginal speculum (Grave's modification of Sims' instrument) (3). The patient is placed in the lithotomy or dorsal position. No digital examination may be performed before the smears are taken. The patient should be advised against douching or other vaginal manipulations before coming to the office for the test. The speculum is inserted in the usual manner except that little or preferably no lubricating material is used. The lubricant may interfere with the staining reactions. The cervix is then adequately exposed and careful visual examination is performed. A glass pipette which must be clean and dry is used to aspirate the secretions from the external os of the cervix. The secretion including the mucus where many significant cells are trapped is transferred to one or two clean glass slides. The secretion is spread out as evenly as possible and the slides which

must never be allowed to dry are quickly immersed in the fixing solution. This solution is made up of equal parts of ether and 95 per cent alcohol. The slides are left here for at least 1 hour although they may remain in the fixer for as long as 2 weeks without undergoing any deterioration. After the slides are fixed they are removed from the fixing solution and without being allowed to dry, they are stained by the method after Papanicolaou washed in alcohol and xylol, and mounted in Canada balsam or similar substance.

One important fact needs to be emphasized again and again. Accurate study and diagnosis of the cytology smears can be done only by an expert. Even gynecologists and pathologists have indicated their inability to interpret cytology tests without the essential preliminary study of a large group of normal cases and positive cancer cases. Every doctor spends at least a year in training in pathology before attempting to interpret cancer from tissue biopsies. Cytology is equally exacting and demands adequate training in cell study before experienced judgment may be developed. It is unfortunate that men with training in neither pathology cytology nor laboratory techniques are attempting to do this work. The inevitable errors caused by poor staining as well as inadequate interpretation have resulted. The method has thus undeservedly fallen into disrepute in the minds of many doctors and consequently many women are denied the benefits of this remarkable diagnostic aid.

The average practitioner may say. Fine the cytological diagnosis of early cancer may well be an important advance in medicine—but only for the expert cytologist and gynecologist. What I want to know is of what help can it be to me—far from any large medical center to which I can send my patients to have these tests performed? These tests are for the benefit of every practicing physician and we shall in a few words show how anyone can make this diagnostic method available to his patients.

It will be obvious that every doctor cannot become an expert cytologist. Hence the procedure of choice is to have in each province, state or district a central laboratory manned

by a group of cytologists and technicians well trained in this work. The slides must not be allowed to dry and the apparent difficulty in mailing the cumbersome jars filled with the ether alcohol solution was soon recognized. It was a major obstacle. To obviate this difficulty Ayre and Dakin have worked out a method by which the slides may be mailed almost any distance in a neat compact and simple fashion. A description of this important technique is now given.

GLYCERINE MAILING TECHNIQUE OF AYRE AND DAKIN (5)

After standing in the ether alcohol fixer for 1 hour or more the slides are removed from the solution. Without permitting them to dry a large drop of glycerine is placed in the center of the secretion zone. A second *clean* slide is placed face to face with the smear and the glycerine spreads out to cover the entire smear area sealing it off completely. It must be noted that each unit is made up of two slides (1) the slide with the smear on it and (2) a clean slide acting as a cover slip. The slides are then placed in wooden or cardboard containers to prevent breakage and are mailed to the cytology laboratory. Airmail is preferable. The slides may remain in the temporary glycerine mounting for 2 weeks if necessary but the best results are obtained if this does not exceed 1 week. Once the slides arrive at their destination the glycerine is washed off and the usual staining routine is carried out. Experimental study of both normal and cancer cells have shown no deterioration of cellular detail or staining qualities.

We see therefore that the use of this diagnostic test is not confined to the gynecological specialists in the large cities. Any doctor with the ability and interest to insert a speculum into the vagina of his patient can take the smears. The mailman brings the cytology laboratory to the physician's front door.

It was with considerable interest and some dismay that I noticed in an abstract of an article (10) on cytology the following as the final paragraph. This method is not an office procedure; it should be interpreted by those trained in cytology and in the smear method of making a diagnosis. Unfortunately any

one who is not familiar with the cytology smear technique might take this misleading statement literally. With the second part of this paragraph we agree heartily. It is an irrefutable fact that without the proper training and experience these smears cannot be accurately studied and interpreted. The first sentence makes a positive statement with which we must disagree, and to which we must strongly object. Cytology is an office procedure. This is the cornerstone upon which the whole structure of the cytological method in cancer detection stands. Remove this and the collapse of the system is inevitable. One need not be an expert to take these smears. Once he has been shown the technique any practitioner can use this method. He does not need specialized training because he is not required to stain and read these slides. Every physician makes wide use of the blood test. Yet how many really understand the diagnostic technique or the serological basis of this procedure? We need and shall have more central laboratories to which the physicians can send their smears for staining and interpretation. It cannot be stressed too strongly that cytology is an office procedure which every doctor can and should use routinely.

While the vaginal and cervical cytology smears, as obtained by the method of aspiration with a glass pipette have given excellent results in diagnosing cancer it must be realized that this technique collects dead cells that have already been desquamated from the growth and have been lying in the vagina or at the os for some time. Search has been made for a method to detect the earliest cellular changes in malignancy and the precancerous state. It has long been known that more cancer develops at the junction of the columnar epithelium of the cervix with the squamous lining of the portio than at any other single focal point of the uterus. Hence a technique which is aimed at the detection and study of the earliest malignant changes in the squamous cells must of necessity procure cells from this region. In April of 1947 Ayre published a paper (4) describing the development and use of the "spatula cytology technique." Previous methods consisted in the aspiration of cells which had already been desquamated.

The spatula technique is a means of collecting the cells before their exfoliation. In this way younger cells are obtained and earlier malignant changes can be recognized than was possible by the use of the older methods. By using this new method of collection the cells are obtained while in a state of excellent preservation before they have become shrunken or the clarity of their cellular detail obscured. Since every cancerous growth is characteristically friable be it in the invasive or pre-invasive stage large numbers of cells (cancer juice) (7) will be obtained when such tissue is gently scraped. In this way an excellent "surface biopsy" is obtained.

In common with all cytology smear techniques, the spatula smear is easy to take, but proper interpretation requires their study by an expert cytologist familiar through practice with the cell types scraped from this area. The first step in the routine cytology test concerns itself with the aspiration of the mucus and secretions from the external os, and their transference to the glass slides. Once this part of the test has been completed the spatula method comes into play. Use is made of a small specially formed wooden spatula to scrape the entire circumference of the squamocolumnar junction. It may be noted that the precise location of this juncture point varies as to whether or not an erosion is present. The spatula technique can be varied slightly to conform with the shape and condition of the cervix. The secretion obtained in this way is transferred to a glass slide which is immediately immersed in the ether-alcohol fixative. The staining is performed in the same way be the cells gathered by the aspiration or the spatula method.

By obtaining routine cytology smears on all patients regardless of their individual complaints, a new cytological picture termed by Ayre the "precancer complex" has been noted (1-4). This group presents the following features: (1) anaplastic squamous cells showing considerable nuclear variability; (2) cornified cells whose nuclei are abnormally large; (3) multilobulation and splitting of the cell nucleus into several separate nuclei in the cornified and precornified cells; (4) abnormally high cornification counts.

Ayre has come to recognize this picture as an indication that a precancerous condition is present. By this is meant nuclear change in the squamous cells at the squamocolumnar junction of a hyperplastic nature with no invasiveness. These lesions are definitely more than an erosion, and more than squamous metaplasia or epidermidization in an erosion, but they have not yet reached the stage of invasive cancer. This cytological picture has been found, and the presence of the lesion confirmed by careful biopsy, in patients who complain of nothing more than a whitish discharge, and whose cervixes may show only a tiny circular reddened area about the os. Were cytology smears not taken on these women the growths may not have come to light until a full blown, far advanced cancer had developed. Routine cytological examination of all females will undoubtedly reveal many early unsuspected, and what is most important, curable cases of uterine cancer.

It may be of interest at this point to mention some of the changes in the morphology of the cells which lead the trained observer to diagnose the presence of malignancy. The size and form of the nucleus are most significant (14). In malignant cells the nucleus is abnormally large in proportion to the size of the cell and the amount of cytoplasm. It tends to grow far beyond the normal limits and to acquire atypical forms. Its structure assumes a characteristic pattern with intensely stained granules or small clumps of chromatin, and a distinct network of filaments centering in the nucleoli. Actual mitoses are rarely seen. The nuclei show considerable variability. Often atypical fragmentation results in binucleate or multinucleate cells. The cytoplasm is usually basophilic. Abnormal vacuolization is a not uncommon finding. Grouping of these cells in clusters and crowding are points of diagnostic value. The cells may overlap to such an extent that it is not possible to focus them in one plane. One sometimes finds bizarre cells (17). These are more common in far advanced cases. Other elements which add to the picture but are in themselves not diagnostic, may be mentioned. These include blood cells, clumped leucocytes, histiocytes and a high degree of cornification.

Most of the discussion up to this point has been centered on cancer of the cervix. Cancer of the endometrium can just as well be diagnosed by the cytology method (9). Here the same problems are encountered but interpretation may be more difficult because there is often less difference between normal and malignant endometrial cells. Hence the diagnosis of cancer of the fundus calls for more expert interpretation than does cervical carcinoma. That the diagnosis of endometrial cancer can be made with a high degree of accuracy has been proved over and over again by several workers (8, 14). The endometrial malignant cells do not show the high variability displayed by the modified squamous epithelial cells found in cancer of the cervix. They are considerably smaller and their variations in form and size are limited. The most frequently found cell types have a cuboidal columnar or spindle-like form and appear singly or in dark staining clusters which can be spotted with the low power. The nuclei are hyperchromatic, enlarged and show variations in size and shape. Histiocytes are as a rule numerous and blood and pus cells are found as in the cervical lesions. It must be remembered that the endometrial cells seen in the cytology smear are desquamated cells and in their journey from the uterine fundus may undergo shrinking or distortion. In cases of doubt the use of a cannula to obtain smears directly from the cavity of the uterus may be of considerable help in arriving at a diagnosis (15).

It has been noted that the spatula cytology technique is selective in cases in which there is invasive and preinvasive cancer. There is also a method which is selective in cases of endocervical and endometrial carcinoma (14). The technique is essentially quite simple. Use is made of a special cannula to which an ordinary glass syringe is attached. The cannula is first inserted into the endocervical canal and the cells are aspirated into the syringe. These are blown onto a glass slide which is placed in the ether alcohol solution. The cannula is then inserted directly into the uterine cavity and secretion from this region is obtained in the same way. The fixing and staining are carried on in the same fashion as for the vaginal and

cervical cytology smears. It is advisable that in cases in which many glandular cells are noted in the vaginal smears the endocervical and the endometrial smears be taken to rule in or out the presence of an endocervical or endometrial cancer.

The following is a representative case of cancer of the body of the uterus which was discovered through routine cytological examination.

Mrs. C. white, widowed 75 years of age came to the gynecological out patient clinic with the complaint of vaginal spotting for the past 2 years. She had consulted her family doctor several times and had been given some injections. Since the spotting persisted she was referred to the clinic. Physical examination revealed a fairly well nourished woman of stated age. Pelvic examination was essentially negative. The cervix was surprisingly clean and healthy in appearance. The vagina showed atrophic changes. No uterine enlargement was noted she was permitted to go home. Routine cytology smears revealed the presence of many cells which were unmistakably malignant and suggestive of a glandular type cancer. Repeat smears next morning confirmed the original impression. The patient was admitted the same day. A dilatation and curettage under anesthesia revealed that the uterus was slightly enlarged and was full of tissue that had the gross characteristics of cancerous material. Microscopic diagnosis was papillary adenocarcinoma.

There are many crude methods of estimating the body estrogen level but none perhaps is more simple nor more accurate than the cornification count in the cytology smears. Studies by Ayre (1) have revealed new evidence of abnormal endogenous estrogen in both benign and malignant uterine neoplasia. Patients who had gone through the menopause exhibited abnormally high cornification counts in the vaginal and cervical smears. Many of these patients were later shown to have proliferative Swiss cheese hyperplastic, or retrogressively hyperplastic endometria. This again suggests that in castrates and post menopausal women some organ other than the ovary (probably the adrenal cortex) takes over the production of some estrogenic substances. In women and in female monkeys the estrogens manifest their presence in the vaginal mucosa by cornification of the cells. This is accompanied by proliferation of the vaginal and cervical squamous epithelium. This growth change is related to the deposition of

glycogen in the squamous cell which is mediated and controlled by the force of the estrogenic stimulus. The vaginal epithelium of the average postmenopausal female is made up largely of basal cells which contain no glycogen and cornification is absent. Under the influence of estrogen the deposition of glycogen may be brought about and cornification of the squamous cells occurs, whether the patient be postclimacteric or following surgical castration. A practical use of this phase of the cytology smear is in follow ups of post menopausal women who are receiving estrogenic therapy.

It may be noted in passing that the diagnosis of cancer by cytological methods is in no way confined to malignancy of the female genital tract (17). Cancer of the prostate, bladder and kidney has been diagnosed from malignant cells found in the urine. Cancer cells in sufficient number to make a diagnosis possible have been demonstrated in the sputum and pleural fluid of patients with cancer of the lung. In gastric cancer the malignant cells are found in the stomach washings. Much research remains to be done in these cancer types, but in uterine cancer the method has proved so reliable as to merit widespread application in cancer detection programs.

A positive smear is not an indication for radical treatment. Confirmation by immediate biopsy is mandatory. It means that cancer is present somewhere in the genital tract and it is the duty of the patient's medical attendants to rest not until the malignant lesion has been found and treated.

We should like at this point to present two illustrative cases which emphasize the value of cytology to the practicing physician.

Mrs. D. aged 70 years was brought in by her daughter for a routine check-up. She had no complaints. Routine cytology smears were positive. Biopsies of the cervix revealed the presence of a pre-invasive carcinoma. Had routine cervical cytology smears not been taken on this patient the lesion would not have been found until considerable growth and invasion had occurred.

Mrs. J. was only 5 years old when she consulted her physician, complaining of loss of weight, loss of appetite constipation and leucorrhea. Cervical cytology smears were positive. The first biopsy was negative, but when the cervix had been amputated and serial sections cut, the cancer was found.

This case is illustrative of the fact that it does occur in young women and that we should never omit careful investigation of a patient because she has not reached the so-called 'cancer age.

These 2 cases, one in an elderly woman and one in a young woman, are adequate evidence of the accuracy of the cervical cytology smear technique in diagnosing early preclinical curable cancer. Serial sections were necessary in one case before the cancer was revealed but if the cytology is positive and correctly interpreted cancer is there. The investigation must be continued until the lesion is found.

DISADVANTAGES

- 1 Specialized training is required in order to make an accurate interpretation (14)
- 2 The test does not show the grade of malignancy although it may occasionally give some hint as to the prognosis
- 3 It does not supply information as to the mitotic activity of the malignant cell or its relationship to the adjoining tissue
- 4 The type and origin of the malignant cell are not always clear

ADVANTAGES

- 1 The test is an unusually simple and painless office test (11)
- 2 It is relatively rapid (1) It can be taken stained and reported in a morning
- 3 It is inexpensive
- 4 It can be repeated as often as necessary without any harm to the patient. Thus it is of great value in follow ups of patients who have had irradiation treatment
- 5 No hospitalization is required
- 6 It permits diagnosis in relatively early stages even before the appearance of clinical symptoms. It also reveals the presence of carcinoma *in situ*
- 7 The characteristic modifications of nucleus and cytoplasm of the cancer cells are more apparent in the smear where the cells appear isolated than in tissue sections where they are in a crowded state
- 8 It is of tremendous value in the screening of large numbers of patients (9)
- 9 It is reliable in the hands of experienced men

10 It does not conflict in any way with the established methods of pathologic diagnosis such as biopsy or curettage (14). On the contrary it is a most valuable complement to them

11 In the control of the menopause the cytological test has a significant rôle to play, giving immediate indication when irregular bleeding may be benign and when dangerous.

We have described the two main cytology smear methods used in gynecology today. The older vaginal method was first described by Papanicolaou in New York City. The cervical modifications were added by Ayre working in Montreal. The vaginal technique has the advantage of simplicity in the taking of the smear. The cervical method which necessitates the use of a speculum carries with it the advantages of more rapid interpretation of each slide as well as greater accuracy.

It is true that the cervical smear takes a little longer time in that a speculum must first be inserted into the vagina. We feel that this disadvantage if it can be so called is outweighed by the fact that a visual examination of the cervix may be done each time smears are taken and visual examination is after all an essential part of every pelvic examination.

The vaginal smear is taken from the pool in the posterior fornix. The cancer cells if there are any are mixed with the normal desquamated cells of the vagina, the vaginal fluid and the debris. Thus the secretion from the fundus and cervix of which the malignant cells are a part is diluted by the vaginal fluid. The cancer cells are separated from each other and appear in the vaginal smear as single cells. Not only are the single malignant cells difficult to spot but the considerable debris from the vagina tends to obscure the telltale cells. These factors often make it difficult to find the cancer cells and cause the interpretation of a single slide to be a long and arduous task.

The cervical smears on the other hand be they aspirated from the os of the cervix or scraped off with a wooden spatula, are obtained before the secretion from the uterus and cervix reaches the vagina. This leads to two important results (1) secretion is undiluted, the cancer cells appearing not singly, but in groups. (2) The obscuring effect of the vaginal

debris is eliminated. Since it is much easier to spot groups of cells than it is to find lone cells, interpretation of the cervical smears is easier and can be done more rapidly.

A further point must be considered. Since the majority of genital malignant lesions in the female arise from the uterus, be it corpus or cervix it is logical to assume, and it has been proved that the cervical method is more accurate than the vaginal one for the smear is taken from the squamocolumnar junction where most cancers of the cervix begin. Comparative smears from the same patient (with cancer of the cervix) show many more malignant cells in the cervical smears than were found in the vaginal slides.

We have briefly outlined a few of the reasons upon which we base our belief that the cervical cytology method is superior to the vaginal technique. It is a very simple matter when doing the test to take three smears: (1) Aspirate the mucus from the os using the usual standard pipette. (2) Scrape the squamocolumnar junction gently with the wooden spatula. (3) Take a vaginal smear using the original method. We feel that those physicians who follow this routine will be convinced by their findings in cancer cases of the superiority of the cervical cytology technique.

I doubt that a paper on cancer of the uterus has been written in which the author does not bewail the situation in which most cancers of the cervix are seen by the physician at an advanced stage when treatment is of small help. If we could get these patients at an early stage of the disease cures could be effected, what we need is some way of diagnosing this dread disease before it has grown into the ulcerating mass which sooner or later causes a hemorrhage that brings a terrified and often exsanguinated woman to the doctor's office. The vaginal tests and the superior cervical cytology tests do fill this diagnostic void. Every physician should learn to take the smears properly and should make their use an integral part of his diagnostic armamentarium.

Late tuberculosis is difficult to treat with much success while early tuberculosis is most amenable to treatment. The hope of the internist who years ago was continually faced with cases of young people dying of tubercu-

losis was that some method might be discovered whereby this dread disease could be discovered before those afflicted had reached the incurable stage. Routine x ray examination of the lungs of healthy persons has provided part of the solution. It must be remembered that a person with early but diagnosable tuberculosis, like the woman with very early cancer of the cervix is to all intents and purposes a healthy individual. No man or woman who feels well consults a physician. The disease is allowed to progress before medical aid is sought. The chest survey technique has obviated this difficulty. Since healthy people are examined it is obvious that many early cases will be found.

Were it not for the marvelous discovery of the Wassermann test for syphilis, we should see many more far advanced cases of generalized and neurosyphilis than we do. Today the "blood test" is a simple routine measure of protection which every enlightened doctor performs as a routine part of his examination, and which every intelligent patient both accepts and expects.

We feel that the cervical cytology test presents a far analogy. In order to pick up cases of early cancer we must search for them among "healthy" women. We must strive toward that ideal state in which every woman will have a periodic check up once or twice a year with the cytology test playing the important rôle which it so truly merits. It must be obvious that if this routine were followed by every woman and every physician, many early asymptomatic and unsuspected cases of cancer of the cervix would be brought to light at a stage where successful treatment could be provided. In this way the mortality from cancer of the uterus which on this continent accounts for well over 20,000 deaths yearly can be should be and shall be lowered.

SUMMARY AND CONCLUSIONS

A discussion is presented of the basic principles of the cytology tests and their application in the early diagnosis of cancer of the uterus.

The vaginal aspiration, the cervical aspiration and the cervical spatula techniques are described, and their relative merits discussed.

It is believed that the cervical spatula test is the most efficient in the diagnosis of very early cervical cancer.

Emphasis is placed upon the importance of having a central laboratory in each district where expert study of these smears may be made.

A simple and efficient mailing technique is described.

Great stress is placed upon the fact that these smears can be taken by every practitioner in his office. This combined with the mailing technique makes it possible for every doctor and every patient to reap the benefits of this modern diagnostic procedure.

A "precancer" complex is noted.

Some diagnostic features of smears in cases of malignant disease are described.

Cancer of the uterine fundus as well as cancer of the cervix can be diagnosed accurately by the cytology method.

These smears provide a reasonably accurate measure of endogenous body estrogen at any one time.

The advantages and disadvantages of the tests are presented.

It is concluded that the use of routine periodic check ups with cytology tests at each visit will do much to lower the present high mortality rate from uterine cancer.

ACUTE NON CLOSTRIDIAL CREPITANT CELLULITIS

W. A. ALTEMEIER, M.D. F.A.C.S. and W. R. CULBERTSON, M.D. Cincinnati, Ohio

ACUTE non-clostridial crepitant cellulitis is an infrequent clinical entity characterized by a rapidly spreading emphysematous infection involving the skin and epifascial subcutaneous tissues accompanied by severe toxemia. Five cases in which adequate cultures showed no clostridia have been reported. Marwedel and Wehring reported 2 cases in 1915 which they attributed to the anaerobic streptococcus. In 1936 Howe reported another case following an appendectomy in which the crepitation extended to the neck, thigh and suprapubic area. Although it was considered to be a case of gas gangrene and was treated with polyvalent antitoxin, repeated cultures revealed no clostridia. Also in 1936 Meloney (7) reported the fourth example in which extensive gas formation was demonstrated clinically and by roentgenogram. His cultures revealed the presence only of the aerobic hemolytic streptococcus *Escherichia coli* and nonhemolytic anaerobic streptococcus. Terrell in 1940 reported the fifth case in which extensive crepitant cellulitis of lower abdomen, inguinal region and thigh originated from a perirectal abscess. Bacteriological studies showed anaerobic streptococcus and *Escherichia coli* the only bacteria present.

Associated with cellulitis crepitation may be caused by several factors which are outlined as follows:

- I. Extrinsic factors
 - A. Physical introduction of air by
 - Severe trauma
 - Improper irrigation of wounds
 - B. Injuries of respiratory organs
 - C. Chemical generation of gas
- II. Intrinsic factors
 - A. Infection by aerogenic bacteria
 - Clostridial bacteria
 - Other bacteria

The infected wound may possess gas introduced extrinsically by physical means such as

severe trauma, improper irrigation of wounds, and injuries involving respiratory organs, or by chemical generation of gas by such agents as hydrogen peroxide.

Rubenstein, Tabershaw and Daniels reported 3 cases with areas of subcutaneous crepitation about lacerations of the hand in patients who had handled an alloy containing 90 per cent of finely powdered magnesium. Schreus reported a series of 15 patients who developed crepitant and aseptic necrosis of muscle a few hours after the accidental injection of benzene thought to be typhoid vaccine.

Gas may be produced within the tissues by various aerogenic bacteria, the most frequent of which are the clostridia. Clostridial crepitant cellulitis characteristically occurs in the subcutaneous or retroperitoneal tissues and is also known as anaerobic cellulitis (4). Aerogenic bacteria other than the clostridia may also produce gas in subcutaneous tissues. These include 3 main groups: the coliform bacteria, particularly *Escherichia coli* and *Aerobacter aerogenes*; the anaerobic streptococci; and various anaerobic gram negative bacilli of the *Bacteroides* group.

MATERIAL AND METHODS OF TREATMENT

The small number of recorded cases and the confusion arising from the available clinical material concerning acute non-clostridial crepitant cellulitis have instigated this report. Of 12 proved cases which we have studied during the past 11 years, 3 patients were seen at the

	103	1,000	Buttock, hip, abdominal wall
1	103.4	7,300	Inguinal area, abdominal wall, flank

Henry Ford Hospital and the remaining 9 at Cincinnati Hospitals. The lesion originated in the perineum in 4 instances, the lower extremity in 3, the inguinal and lower abdominal regions in 2 and the hip, the thoracic wall and the neck in 1 each (Table I).

In 8 patients, the infection complicated operative or accidental wounds. The areas involved in 9 patients were those easily contaminated by fecal, urinary, or respiratory tract discharge. In 7 instances, the patients were colored. The highest temperature was 107.4 degrees F and the lowest 101.6 degrees F with an average of 104 degrees. The white blood count varied between 6,200 and 48,000 with an average of 23,230 and a relative polymorphonuclear leucocytosis.

The youngest patient was 25 years of age and the oldest 59, the average being 45 years. Nine were males and 3 were females. Bacteriological studies showed the bacterial flora to be mixed in all cases, the average number of bacteria per case being 4.3. The incidence of the various aerobic and anaerobic bacteria is shown in Table III.

Among the aerobic organisms the nonhemolytic streptococcus and *Escherichia coli* were most frequently present, while of the anaerobic bacteria the *Bacillus melanogenicus* and the anaerobic streptococcus were most frequent.

The treatment consisted primarily of early and radical incisions of the skin and subcutaneous tissue to points beyond the furthermost limits of the infection. Chemotherapy was used as an adjunct to surgery in 9 patients, 5 of whom were treated systemically with both penicillin and sulfadiazine, 3 with one of the sulfonamides and 1 with streptomycin. Postoperatively zinc peroxide was applied to the diseased tissues as a creamy suspension in water or a stable ointment described by Reid and Altmeier (9) in the 8 later cases, while Dakin's or dichloramine T solutions were used in the 4 earlier cases.

The following case reports are given as examples of the nature of the condition as well as the course of acute non-clostridial crepitant cellulitis.

CASE 7. N. H., a 37 year old negro male who was a known diabetic, was admitted on February 23, 1944 with a history of an infected callus on the lateral aspect of the right foot of 1 week's duration. After the callus had been excised 7 days before admission, the wound became painful, swollen and markedly tender. Examination revealed an acutely ill adult negro male whose temperature was 102.6 degrees F, pulse 96 and respirations 26. There was a deep ulcer of the lateral aspect of the right foot which exuded foul-smelling pus, and the entire foot and lower one-third of the leg showed marked edema and redness. Lymphangitic streaks were easily visible to a point above the knee. His white blood count was 22,150 cells per cubic millimeter, red blood count 3.03 million and hemoglobin 13.0 grams.

On the day after admission incision and drainage of the involved area was done, and a large amount of gas was found in the grayish black subcutaneous tissues about the ulcer (Fig. 1). Postoperatively the wounds were irrigated with Dakin's solution every 3 hours and the patient was given penicillin and sulfadiazine systemically. Smears made of the pus showed numerous streptococci but no bacilli and cultures revealed the presence of aerobic nonhemolytic *Staphylococcus albus*, *Streptococcus viridans*, *Bacillus pseudodiphtheriae* and *Escherichia coli* as well as the anaerobic *Bacillus melaninogenicus* and *staphylococcus*. Two days after operation the crepitation had extended 6 to 8 inches above the malleoli (Fig. 2) and that the signs of toxemia had increased. Believing the infection to be an uncontrollable gas gangrene, his surgeon did a guillotine amputation at the level of the mid thigh on March 3, 1944. Examination of the amputated leg showed the subcutaneous tissues to be edematous, grayish black in color and crepitant up to the knee, but the muscles were not involved. Cultures of the pus showed the same organisms as before except the anaerobic *staphylococcus*. Immediate and striking improvement occurred following operation.

CASE 8. R. J., a 25 year old colored female, was admitted to the hospital on January 18, 1945 with painful swelling of her right labia and a history of having fallen astraddle a fence 3 days previously. Two days before admission she began to have a dull aching pain in the right lower quadrant, but there were no other symptoms suggestive of intestinal or genitourinary tract injury.

Examination showed an acutely ill and toxic colored adult female whose temperature was 104 degrees F, pulse 120 and respirations 28. There was extreme tenderness over an area extending from the right labia to the level of the anterior superior iliac spine. The right labia was markedly swollen, red and painful. Bilateral adnexal tenderness was also elicited on pelvic examination. The white blood count was 43,800, hemoglobin 13 grams, and urinalysis essentially normal.

A diagnosis of acute cellulitis was made and conservative therapy with massive hot compresses and sulfadiazine grams every 4 hours was started.

Within 24 hours the tenderness and induration spread rapidly to involve the entire right side of the abdominal wall and flank extending both anteriorly and posteriorly to the midline. At this time crepitation was present. She was given 200,000 units of penicillin parenterally in the next 24 hours, followed by 15,000 units every 3 hours. No further extension of the infection occurred but her temperature and pulse rate remained high (Fig. 3). A draining sinus developed in the right labium minus on the second hospital day. Although there was no extension of the process there was also no definite recession. On the 9th hospital day an extensive curved incision was made through the skin, and subcutaneous tissues including Scarpa's fascia from the region of the 5th dorsal vertebra posteriorly to the symphysis pubis anteriorly. The wound was irrigated with saline, packed with gauze and a dressing applied, incorporating tubes for irrigation with Dakin's solution. Following operation, improvement in her condition was rapid (Fig. 3). Culture of the wound showed non-hemolytic streptococcus, *Micrococcus flavus*, and *Bacteroides melaninogenicus*. Blood cultures were repeatedly negative. The dose of penicillin was reduced to 10,000 units every 3 hours 3 days after operation and was discontinued 7 days after operation. On February 28, 1945 a split thickness skin graft of the postage-stamp type was done successfully and she was discharged on April 19, 1945 after 92 days of hospitalization.

CASE 10. E. H., a white male of 43 years of age, was admitted to the hospital on March 2, 1945 with a history of right lower quadrant abdominal pain and tenderness of 5 days duration which was preceded by periumbilical pain and followed by nausea. Examination was essentially negative except for tenderness, rebound tenderness, and moderate spasm in the right lower quadrant. His temperature was 102 degrees F and his pulse 100. An appendectomy was done on March 30, 1945 through a McBurney incision by another surgeon. On the second postoperative day his temperature rose sharply to 103.4 degrees F and it was noted that the wound showed signs of infection. Penicillin in small doses of 10,000 units every 3 hours had been given intramuscularly during the preoperative and postoperative period. Five grams of sodium sulfadiazine were given intravenously on the second postoperative day and the wound was reopened for drainage. The patient also developed a marked ileus which was treated by continuous gastric suction. Supportive therapy with intravenous infusions of physiological saline and 5 per cent glucose in water solutions were given, but the infection of the abdominal wall extended rapidly and his condition grew considerably worse.

When seen in consultation on March 26, 1945, he was found to be desperately ill, markedly dehydrated, and moderately distended. His temperature was 102 degrees F, pulse 100, and respirations 30. The appendectomy wound was obviously infected. An area of crepitant cellulitis surrounded the wound and extended inferiorly to a point just below Pou-

Fig. 1. Illustrating the grayish black discoloration of the involved subcutaneous tissues in Case 7. Cultures revealed a mixed bacterial flora including the *Bacillus melaninogenicum* and anaerobic staphylococcus.

part ligament, medially to the midline and laterally into the flank and superiorly to the lower limits of the axillary region. This obviously represented an extension beneath Scarpa's fascia. The overlying skin was intact and showed exquisite tenderness, erythema and edema. The white blood count was 15,300 cells per cubic millimeter with 95 per cent polymorphonuclear leucocytes and the red blood count was 3,500,000. Urinalysis was essentially normal. Cultures taken of the necrotic slough showed the presence of the nonhemolytic streptococcus *Escherichia coli*, *Bacillus melaninogenicum* and the anaerobic streptococcus. A diagnosis of acute non-clostridial crepitant cellulitis of the abdominal wall was made and radical incision and drainage of the cellulitic area was done after preliminary preparation of the patient by adequate hydration and transfusion of blood. The subcutaneous tissues were found to be grayish black in color and crepitant containing a thin malodorous discharge. The operative wound was dressed with topical applications of zinc peroxide ointment covered by layers of moist absorbent cotton and vaseline gauze. In addition continuous gastric suction, interval doses of prostigmine, and injections of 20,000 units of penicillin intramuscularly every 3 hours were used. Supportive therapy was continued postoperatively and the appearance of the wound rapidly improved under daily dressings with zinc peroxide ointment. During his hospital stay he received 5,000 cubic centimeters of whole blood by transfusion. He was discharged on May 17, 1945 with his wound almost healed.

CASE 12. R. B., a 58 year old white male was admitted on May 19, 1946 for operative repair of a strangulated recurrent left inguinal hernia. This was associated with cramping abdominal pain, vomiting and constipation. Previously he had had a bilateral hernioplasty in 1925, a right hernioplasty in 1930, and a left hernioplasty in 1933.

Examination revealed a middle aged white male who appeared to be acutely ill and in distress. His

Fig. 2. Roentgenogram demonstrating gas in subcutaneous tissues of right lower leg in Case 7.

temperature was 98.2 degrees F, pulse 96 and respirations 22. Other findings were within normal limits except for bilateral inguinal scars and a firm tender mass measuring 5 by 10 centimeters over the medial third of the left inguinal ligament. Peristalsis was hyperactive. The white blood count was 8,600, hemoglobin was 11.5 grams and urinalysis essentially normal. Roentgenograms of the abdomen indicated small bowel obstruction.

A diagnosis of strangulated femoral hernia was made and operation on the day of admission revealed a small Richter's hernia which was strangulated in a femoral sac. The bowel was markedly cyanotic but viable. Twelve hours after hernioplasty his temperature rose to 100.4 degrees F. The wound became markedly tender and subcutaneous crepitation was noted at the superior angle. On May 23, 1946 the operative wound was reopened and radical incision and drainage of the surrounding cellulitic area was done. The skin was undermined throughout the full extent of the infection and the incision carried into the adjacent normal tissues. The subcutaneous fat over the left abdominal wall was found to be grossly infected, gray, malodorous and necrotic to the level

Fig. 3. Showing the clinical course and response to adequate treatment in Case 9.

of the 10th rib superiorly to the symphysis and umbilicus medially to the inguinal ligament inferiorly and to a point 5 centimeters beyond the anterior superior spine laterally (Fig. 4). Dressings incorporating zinc peroxide ointment were applied to the wounds and streptomycin in doses of 200 milligrams every 3 hours was given intramuscularly for 9 days followed by 100 milligrams every 3 hours for 10 days. The infection subsided and the granulating wound assumed a healthy appearance within 14 days. Thiersh grafts were successfully applied to the granulating wounds on June 14, 1946 and on June 8, 1946 following which complete healing promptly occurred.

RESULTS OF TREATMENT

Of the 12 cases which were studied the infectious process was completely arrested by treatment in all but 1 in which the infection spread rapidly from the neck into all 3 mediastinal compartments to produce a fatal mediastinitis before penicillin was available. In another diabetic patient in whom the infection obviously had been brought under control death occurred as a result of a coincidental cerebral accident 24 days after the onset of the disease.

The period of morbidity associated with this infection was prolonged the average hospital stay being 68.5 days. After control of the acute infection which usually required 7 to 21 days a further period of disability was required for various plastic procedures and complete healing.

In Case 9 an attempt was made to evaluate primarily the effect of systemic chemotherapy. Although further extension of the cellulitis was prevented the continuing infection and toxemia necessitated incision and drainage. There was no significant difference noted in the clinical course of the 3 earlier patients treated without modern chemotherapy and the 9 later patients. This emphasized the importance of adequate surgery.

The daily application of zinc peroxide cream or ointment (9) to the operative wounds in 8 cases seemed to be a very effective aid in the local treatment. In 1 case, a severe toxemia associated with the infection could not be controlled until dressings with zinc peroxide ointment were started.

The wounds resulting from surgical treatment were so extensive that secondary plastic procedures were necessary in 9 of the patients.

ANALYSIS

Although 12 cases of acute non-clostridial crepitant cellulitis are too few from which to draw many conclusions, the small number of previously reported cases and the meager amount of recorded clinical information warrants their careful analysis. The lesion characteristically was a rapidly spreading necrotizing infection of the skin and epifascial connective tissues of the perineum abdominal wall

buttocks hip, thorax or neck which are easily contaminated by discharges from the intestinal genitourinary, or respiratory tracts. The infection usually developed when invasion of the subcutaneous tissues occurred either primarily from contamination of an operative or accidental wound or secondarily from pre-existing localized infection. The process extended rapidly and superficially over wide areas of the body usually without involvement of the structures beneath the deep fascia. Since the process arose so frequently in the perineum the route of spread was by direct extension beneath Scarpa's fascia into the inguinal region, abdominal wall and flank. The presence of areas of pre-existing necrosis or foreign bodies seemed to favor its development and spread.

The essential pathology was a wet inflammation of the subcutaneous tissues which progressed to necrosis with crepitation within 2 to 5 days after the onset. In those cases in which *Bacillus melaninogenicum* was found the subcutaneous tissues usually presented a grayish black color. Thrombosis of the nutrient vessels of the skin was a prominent finding histologically.

No single type of etiological agent was consistently present and several groups of bacteria seemed to be capable of producing this lesion. The various types of organisms suggested that a symbiotic or synergistic relationship is active in the process. The non-clostridial bacteria which apparently were capable of causing the infection under certain conditions included some strains of the coliform group particularly *Escherichia coli*, the anaerobic gram negative bacilli of the bacteroides group such as *Bacillus melaninogenicum* and *Bacillus thetoides* and the anaerobic streptococcus. In other cases which were similar clinically, cultures revealed the same mixed type of flora in addition to *Clostridium welchii* or one of the other clostridia. These were not included in this report although it seemed doubtful that the clostridia contributed to the severity of the process. It has been impossible to prove by animal experimentation that the anaerobic streptococcus or *Bacillus melaninogenicum* are the causal bacteria since they have been uniformly avirulent for experimen-

Fig. 4. Illustrating the area involved by subcutaneous necrotic infection and the extent of the surgical incision used in Case 2.

tal animals in our experience. However there is strong presumptive evidence that these organisms are virulent for human beings (1). The fact that some members of the coliform and bacteroides groups are pathogenic and gas producing in experimental animals however has been established and there is experimental evidence of marked synergistic activity of groups of intestinal bacteria (2, 3, 8).

The first symptom was pain which usually persisted or developed in and about the wound. Within 24 hours there was an elevation of temperature to 101 to 104 degrees F with a corresponding increase in the pulse and respiratory rates. The pain preceded by 1 to 3 days any obvious swelling or erythema of the overlying skin. As the cutaneous swelling progressed the pain increased, exquisite tenderness to the slightest touch developed and crepitation became perceptible. Early in the infection the patient's general condition frequently appeared to be good but as the lesion extended marked evidence of toxemia became evident with dehydration, temperatures as high as 105 to 107 degrees F, a weak and thready pulse and prostration. The white blood count increased and in 1 instance it reached 48,000. An anemia with falling red blood count and hemoglobin level usually necessitated frequent blood transfusions. In those infections arising in the perineum dysuria and even retention were prominent symptoms.

The clinical course was characterized by the rapidity of extension of the process, almost one-half of the wall of the torso being involved within 4 to 5 days in some instances. Death occurred in 1 case on the 11th day of illness when treatment failed to check the disease.

Early diagnosis, essential for most effective treatment was based on the history and clinical findings. The prognosis was excellent in the patients treated promptly and adequately. Since delay in diagnosis permitted further spread of the infection and increased the duration of morbidity early investigation of wounds in questionable cases is obvious. Roentgenograms for soft tissue detail have aided somewhat in the recognition of gas and in determining the limits of spread in areas not accessible to digital examination.

The principle method of treatment for this condition was early and adequate surgery consisting of radical decompression of the involved area by long and wide incisions through the skin and subcutaneous tissues down to the superficial layer of the deep fascia and peripherally into healthy tissue beyond the further most limits of the lesion. In some instances, it was possible to drain the area effectively by a single linear incision with undermining of the skin flaps. Since radical incisions arrested the process, amputation was usually necessary and the one in Case 7 was done on the basis of a mistaken diagnosis of gas gangrene.

Chemotherapy was used only as an adjunct to surgery. Because of the mixed bacterial flora parenterally administered penicillin in doses of 50,000 or more units every 2 or 3 hours is recommended along with sulfadiazine or streptomycin in therapeutic amounts.

Daily dressings of the wounds with zinc peroxide ointment appeared to aid in the control of the infection which usually was so extensive that fever elevation of pulse rate and signs of toxemia persisted for 3 or more days postoperatively. After control of the infection and development of clean granulation tissue skin grafting was done.

Important general supportive therapy included intravenous fluids for adequate hydration and electrolyte intake repeated whole blood transfusions, and rest.

SUMMARY

The causes of cutaneous crepitation have been reviewed and the two principal types of acute crepitant cellulitis caused by bacteria have been described. Although clostridial or anaerobic cellulitis has been well established, the non-clostridial type has been seldom reported. Twelve cases of non-clostridial crepitant cellulitis have been reported and their clinical features have been analyzed.

A DISCUSSION OF THE USES OF METALS IN SURGERY AND AN EXPERIMENTAL STUDY OF THE USE OF ZIRCONIUM

J. I. BATES, M.D., C. R. REINFERS, M.D., and R. C. HORN, M.D. Philadelphia, Pennsylvania

AS modern surgery has developed repeated efforts have been made to fashion metal appliances to serve in the internal fixation of fractures in restoring the continuity of vessels and in the support of soft tissues as well as for many other uses.

Venable and Stuck (27) in their review of the general considerations of metals for buried appliances in surgery stated that Petronius in 1565 devised a gold plate for the repair of defects of the cleft palate and that Lapeyrolle and Siere in 1775 were the first to place metal wire about a fracture.

Since then metals in the form of wire plates, pins, screws, buttons, and tubes have been used by many surgeons. Beginning in 1905 the work of Sir Arbuthnot Lane stimulated a great interest in the use of buried metal appliances in fractures. He advocated the use of steel and was supported by Sherman in this country who recommended the use of vanadium steel for plates and screws.

Many studies have been made of the toxicity of metals in tissue cultures, the corrosion and weight loss of buried metal appliances in the body, and the histological changes in tissues adjacent to metals.

It has been apparent to Von Brever in 1908 that the metallic particles set free by corrosion could be identified in the surrounding tissues. He also noted that where two different metals, copper and zinc, were implanted close together rhythmic contractions occurred in the underlying muscles, and the connective tissue cells were arranged in the direction of the electric current.

Zetterlin in 1924 studied the reaction of bone to a vanadium metal and stated that in many forms

a metal could modify other elements only at the expense of its own substance and that in an electrolyte this was accomplished by the dissolution of metallic ions to the end that a colloidal solution was formed which conformed to the solution pressure of the metal. He believed that this process underlay the phenomenon which he termed corrosion and that this explained the changes which occur in ordinary steel and iron when they are exposed to the action of an electrolyte such as tissue fluid. Other observers, Orson in 1925, Macmontel in 1935, and Percy and Damany in 1938 also stated that the electrolytic phenomenon was the important factor in causing the unfavorable reaction of bone to the metals used for ortho-synthesis.

Venable and Stuck (25) and Venable, Stuck, and Beach (3) deserve great credit for calling the attention of American surgeons to some of the fundamental principles involved in the evaluation of corrosion and tissue reaction. They stated that corrosion is the deterioration of a metal in its fluid environment and is due to electrolysis. In 1916 they performed a number of animal and chemical experiments from which they concluded (7) that all the metal commonly used in surgery were subject to electrolytic activity in body fluid, and that the extent of tissue damage was roughly equivalent to the amount of galvanic action which took place between the metal.

The theory that the electrolytic action of metals in tissue fluid is the important factor is not held by all observers. Moncreaux, Myers, and Olette in 1915 studied the influence of metals on the growth of fibroblasts and epithelial cells in tissue cultures. They expressed the opinion that two metals of identical potential in solution did not have an appreciable effect from their contact. Later in 1915 they stated that the importance of the electrolytic phenomenon

created by the association of two metals was negligible as compared with the toxicity of the metal itself.

In 1940 and in 1942 Bothe Beaton and Davenport (3) and Bothe and Davenport (2) reported experimental work which led them to believe that bone reactions were not closely correlated with the magnitude of potential differences but remained characteristic for a given metal or alloy. They stated that electrolysis was not the primary cause of unfavorable bone reactions but that these are determined by the physical and chemical properties of the metal itself. The solubility and the degree of toxicity of the dissolution products appeared to them to be the chief factors in unfavorable reactions.

From this review it is apparent that the fundamental principles involved in the reaction of metals to human tissues are not agreed upon by all investigators. Any metal which is contemplated for use in tissues on a permanent or semipermanent basis should be chemically and physically inert and cause no electrolytic phenomena. Having fulfilled these criteria the metal may be tried in experimental animals to observe tissue reaction and toxic effects and then used clinically in any way that the metal can be mechanically fashioned.

With regard to this latter point Venable (23) has stressed the fact that there is much more to the detail of the requirements of physical fitness than shape and size so that all metals must conform to necessary specifications as to strength, durability, malleability, fragility, torsion and resistance to fatigue as well as resistance to corrosion. Also there are certain metals which have inherent properties best suited for suture material and others for plates and screws and still others for tubes.

Since 1920 surgeons have endeavored to find a suitable 'alloy' which will have no deleterious effects in the body. Due to the variation in the manufacture of alloys, one of the most intricate of technical specialties, it was impossible to standardize the physical and chemical properties adequately for uniform clinical results. In the past decade three alloys—vitallium, ticonium, and 18-8-SMO stainless steel—have been developed which are passive enough for use in the human body.

Vitallium is an alloy of cobalt, chromium and molybdenum. The material is cast and is very hard. It has been used for bone plates (5, 6, 29), cranioplasty (9, 19), reconstructive orthopedic appliances (16, 26) and common duct reconstructions. The faults of vitallium are its inability to be worked cold or to be drawn into wire and the fact that casting is necessary.

Ticonium is an alloy of nickel, cobalt, chromium and molybdenum. It has been investigated by Campbell, McIrowaky and Tompkins (4) who found it to be strong, rather light, and also malleable. In a study in which ticonium and vitallium were used for cranioplasty in dogs they found that cast ticonium, to which a small amount of beryllium had been added for casting purposes, was cytotoxic. However, the wrought ticonium without beryllium showed the same inertness as vitallium. We have been unable to find reports of the clinical use of ticonium.

18-8-SMO stainless steel contains roughly 18 per cent nickel, 8 per cent chromium, 2 to 3 per cent molybdenum and the remainder iron, manganese and carbon. This steel can be machined and it has a high tensile strength. The disadvantage of using it in the body is that there is thought by some to be a slow, steady galvanic action which over a long period of time produces irritation (27). This has been disputed by some surgeons who have used this steel for cranioplasty plates and screws, as well as wire. However, sufficient time has not elapsed for an adequate evaluation of its clinical application.

The fourth metal that has been reported as being useful for surgical application is a basic element, tantalum (8, 20, 22). It is a metal which is extracted with difficulty from deposits which are sparsely distributed over the earth's surface. It is strong, tough, and malleable and can be drawn into wire or machined. It is inert in tissues and has been used in the form of plates for cranioplasty, screws, foil and wire with considerable success. The disadvantages of tantalum are that it cannot be cast and is extracted with difficulty from raw material that is rare. It is expensive.

The purpose of this investigation is to present a preliminary evaluation of zirconium

another element for use in surgery. There are no reports in the literature that we have been able to find of the use of this metal in experimental animals or human beings. The following presentation will be used: (1) zirconium, its physical and chemical properties; (2) the electrolytic properties of zirconium; (3) the reaction of rectus fascia and muscle to zirconium wire; (4) the reaction of bone to zirconium screws and intramedullary pins; (5) the repair of cranial defects of dogs with zirconium plates; (6) the reaction of brain to zirconium foil; (7) the reaction of brain to silver tantalum and zirconium hemostatic clips.¹

ZIRCONIUM, ITS PHYSICAL AND CHEMICAL PROPERTIES

Although zirconium (1, 7) is eleventh in the table of abundance of elements in the earth's crust, it has been available to man in a useful form only in the last few years. In 1925 a method of making ductile zirconium was developed and since then rapid advances have been made in the use of zirconium in industry, particularly in the electronic industry. The extraction and separation of zirconium from its raw state as the silicate and the oxide is still difficult.

Some of the physical properties of zirconium are compared with those of tantalum and 18-8-SMO stainless steel in Table I. The significance of these facts will be discussed at the end of the paper.

Although at high temperatures zirconium is extremely active, it is rather surprising that below 200 degrees C. zirconium is almost inert.

Items 5, 6, and 7 will be considered in succeeding papers.

Fig. 1. Diagram of the circuit used for the electrolytic studies. G, Sensitive galvanometer; C, calomel half cell; Pss, physiological saline solution; M, metallic strip. The final steady readings after polarization had occurred were: aluminum 200, copper 50, silver 7, tantalum, 0 to 0.5 and zirconium 0 to 0.5 microamperes.

and corrosion resistant. Fully annealed zirconium is soft and malleable and can be drawn and shaped easily. It work hardens to a considerable degree but also has a high work capacity. Approximately 15 minutes at 750 to 800 degrees C. will fully anneal zirconium.

Chemically one of the most important properties of ductile zirconium is its corrosion resistance. The alkali resistance of zirconium is greater than that of tantalum. The two metals show the same resistance to hot concentrated hydrochloric acid. Zirconium is corroded much less than 18/8 stainless steel by hot 75 per cent phosphoric acid.

TABLE I—FUNDAMENTAL FACTS CONCERNING ZIRCONIUM, TANTALUM AND 18-8-SMO STAINLESS STEEL

Metal	Yield strength in psi		Tensile strength in psi		Ductility per cent		Specific gravity	Modulus of elasticity in psi
	Annealed	Unannealed	Annealed	Unannealed	Annealed	Unannealed		
Zirconium	20,000	55,000 to 80,000	45,000 to 60,000	60,000 to 80,000	30 to 40	to 5	6.54	1,000,000
Tantalum	5,000 to 30,000	30,000 to 70,000	5,000 to 60,000	30,000 to 80,000	20 to 40	1	6.61	1,200,000
18-8-SMO stainless steel	20,000 to 30,000	Not used in this form	90,000 to 95,000	Not used in this form	35 to 60		7.85	30,000,000

The thin fibrous capsule around the pin and the relative absence of reaction are demonstrated. b, Section outlined in a, $\times 75$. This shows the nature of the thin ring of chronic inflammatory tissue and the fibrous capsule which formed around the aluminum pin.

THE ELECTROLYTIC PROPERTIES OF ZIRCONIUM

The importance of the electrolytic action of metals in relation to tissue reaction has been discussed. Venable and Stuck (25) concluded

that the current flow registered by a microammeter with vitallium and stainless steel in physiological saline solution was a good index of how much tissue reaction might be expected

The fascia at the lateral side of the patella was incised and the patella dislocated medially. A hole was drilled from the articular surface of the tibia vertically into the medulla of the tibia, and a zirconium pin 2.0 centimeters in length by 3.0 millimeters in diameter was inserted. The patella was then replaced and the joint capsule closed with interrupted black silk sutures. On the medial aspect of the tibia below the knee joint a hole was drilled through the cortex into the medulla and into the cortex of the opposite side. A zirconium screw 1.6 centimeters by 3.5 millimeters was then inserted. The skin was closed with a continuous subcuticular black silk suture. The dogs were sacrificed after 6 and 12 week periods. The screws and pins were removed after decalcification with formic acid and sodium citrate. The bones were imbedded in paraffin and the sections were stained with hematoxylin and eosin.

Results. Grossly there was no necrosis softening. Infection or discoloration evident in any instance. The screws and pins did not become loose and there was no evidence of gross osteolytic action. The heads of the screws were covered with a capsule continuous with the periosteum of the bone. The articular cartilage had regenerated over the end of the pin in every case and the point of entrance of the pin could no longer be seen.

Microscopically the intramedullary pins provoked only minimal foreign body reaction. The bony trabeculae were compressed around the pin and at the 12 week period there was a delicate fibrous connective tissue capsule in a few cases (Fig. 2). The sections of cortex showed proliferation of the periosteum around the head of the screw which was denser and thicker at the 12 week period. In some sections there were small areas of chronic inflammatory tissue which were limited to the immediate vicinity of the screw.

DISCUSSION

After evaluating the physical chemical and electrolytic properties of zirconium as well as the experimental evidence of the minimal reaction of fascia muscle and bone to zirconium we believe that this metal has a place in surgery.

Zirconium is abundant in the raw state. The cost of zirconium has not as yet been stabilized. However it is anticipated that it will be considerably less than tantalum although not as cheap as stainless steel. Furthermore the manufacturers anticipate that increased industrial demand will permit cheaper production as well as improvement in the method of making ductile zirconium. The fact that zirconium is an extremely plentiful metal whereas tantalum is rare in the raw state may play a significant rôle in the development of zirconium. Chemically zirconium is extremely inert.

Zirconium is an element which seems to be free of the variations in electrolytic activity found in some metals used in surgery. This electrolytic passivity has been confirmed by the experimental work in physiological saline and bone reported above. However, whether or not electrolysis is the fundamental factor in the tissue reaction produced by metals cannot be deduced from these results. A detailed study of the electrolytic properties of all metals used in surgery should be done in the near future through the close co-operation of a physicist and a research surgeon. There is no doubt that in the future new metals will be tried experimentally and clinically and it will be necessary that these fundamental principles be known.

The importance of avoiding the use of different metals in the same operation has been stressed by Venable (23). If a vitallium plate is fixed with steel screws, there will be an intense reaction. Key recently reported 3 cases of fractured femurs in which Neuman stainless steel pins were fixed with screws of different types of stainless steel causing an intense reaction necessitating removal of the pins. There is a tendency in most operating rooms for metal appliances to accumulate. Many of the metals particularly the screws have a similar appearance and for this reason there should be a uniform method of marking each metal even each small screw so that the surgeon who is directly responsible for success or failure of the operation may have uniform composition of materials.

It should be emphasized that both tantalum and zirconium are pure elements and as such

may have properties superior to the surgical alloys. In industry (12) it has been found that alloys are subject to a phenomenon known as stress corrosion. In other words even though initially an alloy may be corrosion resistant over a long period of time with repeated stresses and strains the individual elements composing the alloy may be changed in their relative physical relationships. This change is sufficient to allow corrosion. It is probably also true that alloys such as titanium, titanium and 18-8-SMO stainless steel which are used as supporting bone plates being subjected to multiple stresses and strains over 30 to 40 years may ultimately change from inert metals to active and dangerous metals. This "stress corrosion theory" has been demonstrated by metallurgists for industrial alloys but has not been confirmed as yet for surgical appliances.

The physical properties of zirconium are such that in the cold state it can be drawn into rods, ribbon, and wire of varying degrees of malleability. It can be rolled into plates and machined into screws adaptable for neurosurgical or orthopedic purposes. Foil has been rolled to 0.001 inch and with further refinement of technique thinner foil may be obtained. Tubes of various degrees of malleability have been made for biliary, vascular and urological surgery.

It is not the purpose of this paper to discuss the relative merits of tantalum, stainless steel and zirconium for suture materials, bone plates, and intramedullary pins but the facts recorded in Table I are fundamental for the proper evaluation of the part zirconium will play in surgery. A few simple definitions of the terms used will help to clarify the table.

Annealing is a method of removing work stresses and altering crystal size. Tensile strength is the stress required to produce a permanent break of the metal. Yield strength is the stress required to produce a permanent deformation that is to say, metals act like an elastic band for which there is a point when the material will be overstretched and will not spring back to its original length. Modulus of elasticity is the stress required to produce a unit deformation. These 3 factors are expressed in pounds per square inch (psi).

Ductility or the ability to bend the metal is expressed as the percentage elongation.

The specific gravity of tantalum is more than twice that of zirconium and stainless steel whereas the modulus of elasticity of zirconium is about half that of tantalum and stainless steel. In other words it takes half as much energy to move a unit of zirconium as it does to move a unit of tantalum. Because of this a 0.015 inch zirconium plate is easier to bend than a plate of tantalum of similar thickness. Consequently it might be necessary to use a thicker plate of zirconium which however, would still weigh less than the tantalum plate. (Specific gravity of tantalum is two and a half times greater than zirconium.)

For purposes of suture material the tensile strength is an important factor. Stainless steel with a value of 90,000 psi is superior to the annealed varieties of tantalum and zirconium which are approximately 50,000 psi. Unannealed tantalum and zirconium may have tensile strengths as high as 130,000 psi but the ductility is decreased from about 30 per cent to 2 per cent. This means that the unannealed varieties of zirconium and tantalum are probably too brittle for suture material. Actually the problem is not as simple as this and includes the evaluation of the roughness of the surface to prevent slipping and springiness of the knot with double and triple throws which might cause unwinding. A fine braided zirconium wire is being developed which may prove to be very useful.

The surgeon must decide by careful experimental and clinical methods the relative inertness in tissues and adaptability of the metals for his particular needs.

Experimentally in dogs zirconium appears to be tolerated well. In this study we have shown that zirconium wire causes a minimal reaction comparable to steel and tantalum wires when placed in the rectus muscle and fascia of dogs.

The gross and microscopic reaction of bone to zirconium has been demonstrated to be minimal at 6 to 12 week periods in the tibiae of dogs. It is well known that reaction to bone is extremely hard to evaluate and a long period of time is important before categorical statements should be made.

In a later paper on hemostatic clips a more delicate method for the evaluation of tissue reactivity will be discussed. Strips of silver tantalum and zirconium were placed in the brain of dogs and the results, confirming the work of Pudenz showed that silver causes a severe reaction whereas tantalum is almost completely inert. Zirconium was not quite as inert as tantalum but certainly caused less reaction than silver.

The introduction of a new metal into surgery is a gradual process requiring careful experimental and clinical observations. We believe that zirconium causes as little reaction as several metals that are used at present in surgery and also has physical properties which will be adaptable to certain surgical appliances and material.

SUMMARY AND CONCLUSIONS

1. The use of metals in surgery and the principles of the reaction of tissues to metals have been discussed. Four metals, vitallium, titanium, 18-8-SMO stainless steel and tantalum have proved to be sufficiently passive for use in the human body.

2. A new metal zirconium has been studied experimentally. Zirconium is an element which has similar physical properties to tantalum but it is two and a half times lighter than tantalum. They are both electrolytically inert. The tissue reaction caused by zirconium sutures placed in the rectus fascia of dogs, was minimal. Intramedullary zirconium pins and bone screws provoked only very slight reaction at 12 weeks.

3. Zirconium which has proved to be a lighter more malleable and cheaper metal

than tantalum warrants further study regarding its use in surgery.

REACTIONS TO MORPHINE IN AMBULATORY AND BED PATIENTS

JULIUS H COMROE Jr., M.D., and ROBERT D DRIPPS M D Philadelphia, Pennsylvania

IT has been reported that the incidence of vomiting following the administration of therapeutic amounts of morphine is very low. For example vomiting followed the use of morphine in only 2.3 per cent of 776 patients at the Massachusetts General Hospital (6). On the other hand an examination of certain physiological studies of morphine reveals a very high incidence of vomiting 57 per cent (5) and 93 per cent (2) following the administration of 16 milligrams and 100 per cent (9) after the injection of 30 milligrams of morphine. Since it is unlikely that groups of individuals vary so widely in their response to a drug it seems probable that different experimental conditions might be responsible for the differences. Analysis of the groups with low and with high incidences of vomiting revealed one point of importance the former group represented postoperative cases confined to bed while the latter was composed of normal ambulatory subjects. Batterman has reported that side reactions occur in 70 per cent of ambulatory patients given demerol but in only 27 per cent of bed patients. Similar studies following the use of morphine have not been reported with the exception of one study dealing with 5 subjects given morphine (8) in whom nausea usually followed attempts to get up and was relieved by recumbency. In order to test whether a change to the ambulatory state was responsible for the marked increase in vomiting following the administration of morphine we subjected large numbers of normal individuals and patients to the drug. This study confirmed the suspicion that vomiting produced by morphine is much more frequent in the ambulatory condition. In addition, information has been gathered bearing upon (a) other side effects of morphine, (b) their length of action, (c) possible counteraction of side

effects by food, pain, atropine or amphetamine or avoidance by the substitution of demerol.

METHODS

Studies were done upon 211 normal ambulatory individuals and 200 patients confined to bed (ages 19 to 61). No subject knew whether a drug or a placebo was administered and the great majority did not know that the studies involved the use of morphine. Morphine was administered orally, subcutaneously or intravenously in dosage ranging from 8 to 30 milligrams. In 16 cases atropine (0.6 mgm) and in an additional 23 subjects amphetamine (20 mgm) was given along with the morphine. A complete report of all symptoms and their time of occurrence (covering a 24 hour period) was written by each of the medical student subjects (172) in the case of hospital patients (239) symptoms were recorded at intervals by one of us with the assistance of Dr. James Hardy. The subjects were usually ambulatory immediately after the injection except that some in whom the respiratory and circulatory effects of morphine were studied (34) did not become ambulatory until 1 to 2 hours after injection.

RESULTS

Character of symptoms. The main symptoms experienced following the administration of morphine were (in approximate order of frequency) dizziness, nausea, itching (especially of nose), feeling of warmth (particularly in the face), sensations of weakness, heaviness of limbs and head fatigue or depression, visual blurring, euphoria, headache, miscellaneous gastrointestinal symptoms (such as epigastric fullness, increased peristalsis, belching or abdominal pain), vomiting, dryness of mouth, difficulty in urination, tremor, fatigue of tonic neck muscles and hiccough. In addition those receiving morphine intravenously often noted temporary paresthesias, palpitation and

TABLE I — FREQUENCY OF SYMPTOMS IN AMBULATORY SUBJECTS AFTER THE ADMINISTRATION OF PLACEDOS OR MORPHINE.

	Placido	Subcutaneous morphine			Intravenous morphine	Oral morphine	
Dosage (mgm.)		3	5	20	5	5	20
No. of subjects	20	5				64	
No. symptoms	23%	9%			85%	41%	44%
Nausea		20	20%	100%	85%	36	26
Vomiting		9	3	30	44	5	14
Diarrhea		26	64	100	73	8	
Warmth		8	67	60	73		4
Itching		26	70	70	5		7
Sleepiness, fatigue or mental depression		5	70	60	70		
Euphoria		17	3	40	60		
Visual blurring		9	3	50	23		7
Minor gastrointestinal complaints		18	3	40	7	5	18
Headache				40	40		20
Dryness of mouth		17	3	20	7	3	

lessening of respiratory effort immediately after the injection.

Frequency of symptoms. Table I shows the frequency of symptoms following administration of various dosages of morphine subcutaneously intravenously and orally. It may be noted in Table I (all data obtained from normal medical students) that 2 to 4 times as much morphine had to be administered orally to produce an incidence of symptoms similar to that following parenteral administration. Because of this low incidence of side effects one might favor use of morphine by the oral route. We are inclined to believe however that these minimal side actions are associated with decreased analgesia and are the result of incomplete absorption. This remains to be proved experimentally.

We have found no evidence that the use of the intravenous route reduces the incidence of nausea and vomiting as noted by Pearman.

Length of action of morphine. In Table II are shown the time for onset of nausea and vomiting and the persistence of nausea following the administration of morphine alone and in combination. It should be emphasized that though nausea following morphine usually occurred within 2 hours, in some cases it was de-

layed 3 to 6 hours. More important was the finding that when vomiting occurred this was usually delayed 3 to 5 hours but occasionally did not develop until 7 to 8 hours. It is usually considered that the effects of morphine wear off in 4 to 5 hours (9) while this may be true of the analgesic action it does not hold for the gastrointestinal effects.

Modification of symptoms produced by morphine.
1 By bed rest. Two hundred patients were given 15 milligrams of morphine subcutaneously as part or all of preoperative medication. These patients were questioned by the anesthetist just before operation concerning the development of nausea or vomiting. Only 14 (7 per cent) reported nausea; this was annoying in only 2 (1 per cent) and in these retching occurred. These figures should not be compared with those in Table I since the preoperative cases were followed for only 15 minutes to 3 hours. However 68 of the 200 were followed for more than 1 hour and of this group the incidence of nausea was 12 per cent. In 19 studied for more than 2 hours, the incidence of nausea was 12 per cent. In 25 normal ambulatory subjects given 15 milligrams of morphine 50 per cent of those ultimately developing nausea noted it within the first hour and 90 per cent within the first 2 hours.

More conclusive evidence of the importance of position in the production of nausea and vomiting is the following: 19 normal subjects were given 15 milligrams of morphine intravenously or subcutaneously in the supine position. Twelve subjects lay down for 1 to 2 hours after injection; during this time only 1 subject developed nausea. Immediately after arising 3 developed nausea and within another hour 5 more became nauseated. The 7 other subjects lay in bed all day; none developed nausea.

In practically every instance nausea caused by morphine could be relieved by the subject's lying down. It often recurred shortly after arising. In 2 cases nausea was brought on merely by rolling the subject from his back to one side and in one subject by lateral rotation of the head.

2 By food in stomach. In some subjects, nausea occurred shortly after the ingestion of food. One group of subjects ingested 15 milli-

TABLE II—TIME IN HOURS FOR ONSET AND OF DURATION OF NAUSEA AND VOMITING FOLLOWING SINGLE DOSES OF MORPHINE

Drug and dose—mgm.	Route	Nausea				Vomiting	
		Onset		Duration		Onset	
		Range	Average	Range	Average	Range	Average
5 morphine	S.C.	3-3	7		7	-6	3.7
50 morphine	S.C.	5-4	8		7	5-7	5.5
5 morphine	LV	0-4.5		5-35	5	3-8	6
5 morphine 6 tropine	S.C.	2-6	3			5-6.5	5.5
5 morphine 50 amphetamine	S.C.	0.5-6	2.7	2-3	4.6	1-7	2.6

grams of morphine 3 hours after the last meal the total incidence of gastrointestinal complaints was 13 per cent. A similar group ingested the same amount immediately after lunch 35 per cent reported symptoms referable to the gastrointestinal tract.

3 *By atropine* The incidence of nausea and vomiting was not reduced by atropine. When 0.6 milligram of atropine was given simultaneously with 15 milligrams of morphine (subcutaneously) 69 per cent of the ambulatory subjects became nauseated and 24 per cent vomited. No marked differences occurred in the incidence of other symptoms (as compared with morphine alone) except for a greater occurrence of visual complaints and dryness of the mouth when atropine was added.

4 *By amphetamine* The incidence of nausea and vomiting was not reduced by the addition of 20 milligrams of amphetamine subcutaneously though the onset may have been delayed. The average time of onset of nausea in this group was 160 minutes as compared with 100 minutes in the group receiving morphine alone (Table II). Because of difficulties in controlling the extent of ambulation in different groups this difference cannot be considered to be significant. However we have observed that severe nausea following morphine alone was relieved completely by an injection of amphetamine the effect was temporary and nausea recurred in severe form in $1\frac{1}{4}$ hours.

5 *By pain* In 10 subjects severe pain (bends) was produced by exposing them to equivalent altitudes of 38,000 feet in a low

pressure chamber. Following injection of 10 milligrams of morphine nausea occurred in 60 per cent despite the presence of intense pain.

6 *By substitution of demerol* An experiment similar to that recorded under paragraph 5 was carried out, substituting 100 milligrams of demerol for morphine. Six of the 10 subjects participated in both experiments. Following the administration of demerol nausea occurred in 50 per cent, severe dizziness occurred in 80 per cent, drowsiness in 60 per cent, tremor in 40 per cent, and dryness of the mouth in 40 per cent. In experiments upon pain free normal subjects on a tilt table we have noted that severe nausea usually follows tilting into the feet down position if demerol had been administered. The occurrence of marked symptoms following the use of demerol in ambulatory patients has been noted previously (1).

DISCUSSION

It is becoming evident that clinical studies of a drug new or old must not be confined to resting subjects or patients. A previous study of the action of morphine in patients tilted upright revealed an important action upon the circulation that had not been noted in supine subjects (3). The present study reveals the frequent occurrence of symptoms in the ambulatory state that occur rarely in bed patients.

These results suggest that morphine should not be given without warning to ambulatory patients or to patients who may become ambulatory shortly after the injection. They also

indicate that when morphine must be given to patients in whom vomiting might be highly undesirable or even disastrous, emesis may be prevented by (a) insistence upon the supine position (b) administration of the smallest and least frequent dosage possible, and (c) restriction of food intake. There appears to be little reason to combine either atropine or amphetamine with morphine in an attempt to reduce the incidence of nausea or vomiting.

The cause of the more frequent nausea and vomiting in the ambulatory state remains to be determined. It does not appear to be related to the circulatory action of the drug (3). It may be related to reflexes set up in the vestibular apparatus due to change in position; this appears to be the cause of the nausea induced by lateral rotation of the body or head in bed patients. Other reflexes such as traction reflexes set up by the pull of the abdominal organs in the erect position cannot be excluded in the other subjects; however, there is no reason to believe that these would produce the dizziness and light-headedness that occurred in the ambulatory state.

Postoperative nausea or vomiting is often attributed to factors other than morphine because of the long interval between the nausea and the injection of morphine. These studies show that nausea and especially vomiting may

often be delayed 6 to 8 hours after a single administration and may last an additional 4 to 5 hours.

SUMMARY AND CONCLUSIONS

1. Nausea and vomiting occur rarely following the use of morphine in bed patients, but very frequently in ambulatory patients.
2. Nausea and vomiting can be prevented as a rule by using small doses of morphine, or by insisting upon bed rest.
3. The frequency of occurrence of these symptoms is not lessened by administration of atropine or amphetamine.
4. Other symptoms that follow the administration of morphine are discussed in relation to dosage and mode of administration.

RE-EVALUATION OF THE ROLE OF THE PYLORIC ANTRUM IN MARGINAL PEPTIC ULCERS

J A SCHILLING MD and H E PEARSE MD FACS Rochester New York

SINCE Wolfer first devised a gastroenterostomy anastomotic or marginal peptic ulcers have continuously confronted the surgeon. The increasing though still incomplete knowledge of the phases of gastric secretion has markedly influenced the trends in the surgical treatment of peptic ulcers. The effect of the pyloric antrum on the gastric phase of digestion has been a subject of much discussion. The influence of the antral mucosa on the incidence of marginal peptic ulcers has also been debated. The following presentation will be concerned with the rôle of the pyloric antrum in marginal jejunal ulcers experimentally in the dog.

The researches of Pavlov established the cephalic gastric, and intestinal phases of gastric secretion. A fourth continuous phase of gastric secretion has been recently emphasized by Sandweiss. Fundamental contributions to this general subject have been made by Beaumont, Cannon, Carlson (14, 15), Alvarez, Babkin (8), Ivy (37), Wolf and Wolff and a host of other investigators. Their works may be referred to for reviews of the broader aspects of this presentation. Concomitantly the development of gastric surgery was affected by the research of the above investigators. Marginal jejunal ulceration following gastrointestinal anastomoses has been the stimulus of much surgical research.

The first marginal ulcer in man was reported by Braun in 1899. Watts in 1903 described the first marginal ulcer occurring spontaneously in the dog. Following Bayliss and Starling's discovery of secretin, Edkins (20, 21) described a substance that he had isolated from the pyloric mucosa of cats and dogs. This substance he designated gastrin. After extraction and intravenous injection it

was capable of stimulating the acid secretion of the fundic glands of the stomach. In the succeeding years there was considerable debate concerning the actuality of gastrin. Lim in 1922 found that pyloric extracts caused gastric secretion. Extracts of the cardia and duodenum were less active. He felt that differences of opinion were due to different methods. Ivy (35, 36) using a completely denervated subcutaneously transplanted gastric pouch conclusively demonstrated the origin of a humoral factor from the pyloric region capable of stimulating gastric secretion. He suspected that this substance was histamine. Komarov (43) in 1938 reported a protein like substance having a specific secretagogue effect on the fundic glands of the stomach. It could be extracted in a histamine free form from the pyloric mucosa and to a lesser extent from the duodenal mucosa of dogs and hogs. In 1942 Komarov (44, 45) reinvestigated the problem of gastrin. He was unable to isolate the substance in a crystalline form and was unable to understand completely its mode of origin and transportation. Thus it was impossible definitely to establish gastrin as a true hormone. He felt that the crudeness of the extracts of many previous investigators had led to much of the confusion of the knowledge concerning gastrin. Friedman has recently noted a specific secretagogue in the pyloric mucosa of the dog. This subject has been very completely reviewed by Ivy (38), Schiffman (68), Komarov (45), Uvnas, Babkin (5, 7, 8) and Ihre in recent literature.

In conjunction with the attempts to prove or disprove the presence of a specific hormone by direct extraction from the pyloric mucosa, many investigators used an indirect approach in an attempt to assay the effect of the pylorus on gastric secretion. The relationship of the pylorus to marginal jejunal ulcer was suspected first by von Eiselsberg (81). The effect of various operative procedures on gastric

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, New York, September 8-12, 1947.

secretion and postoperative complications has been most recently reviewed in a paper by Wangensteen (83) and his associates. Pavlov, Lonnquist, Gross, Krzyshkovski, Sawitsch and Zelfony, and Grindley noted that introduction of food and secretagogues into isolated pouches of the pyloric antrum caused increased gastric secretion. Using Pavlov or Heidenhain gastric pouches, Smidt, Portis and Portis, Steinberg (73), Shapiro and Berg, and Klein noted a decrease in secretion in the pouches after resection of the pylorus. Thompson reported a decrease in acidity of the stomach that was roughly proportional to the amount of the pylorus removed. Lewis observed a decrease in gastric secretion after resection of the pyloric mucosa with maintenance of the normal gastroduodenal muscular continuity. Wilhelmj and his associates (33, 86-89) in a series of papers on the general subject found a decrease in the total volume of gastric secretion in whole stomach pouches after pyloric resection. Wangensteen (83) using histamine as an exciting agent found no change in the secretory response after removal of the pylorus. Grindley reported little change in the total volume of secretion in a Pavlov pouch after resection of the pyloric antrum. Priestley and Mann felt that the pylorus exerted little effect. Masaki observed a marked increase in the secretion of a previously prepared Pavlov pouch with frequent gastroduodenal ulcers after exclusion of the pylorus in rabbits and a simple gastroenterostomy. This did not occur after excision of the pyloric segment. Uvnas believed that the cephalic phase of gastric secretion was controlled by a combined neurohumoral mechanism identical in principle with that of the gastric phase. The pylorus was considered an integral part of this mechanism. Evidence for this were the following observations. Gastric secretion during vagal stimulation ceases, or is diminished if the blood supply of the pylorus is interfered with or the pyloric mucosa is anesthetized or resected. During vagal stimulation a secretagogue is liberated from the pyloric region. These secretagogues may be extracted after the method of Komarov and when injected intravenously cause only slight secretion. However when injected during vagal stimu-

lation an abundant secretion occurs. This extract was not histamine. Babkin and Schacter (6, 7) questioned and later denied the above conclusions basing their statements on the fact that in Uvnas' acute experiments, depression of gastric secretion was due to operative shock, and not due to resection of the pylorus. They found no evidence that close co-operation between vagi and pylorus was necessary for production of gastric juice. The two mechanisms could work separately. Wilhelmj (88) believed that an intrinsic pylorofundic reflex did not exist. In summary the general consensus is that a gastric humoral factor exists that is capable of stimulating gastric secretion after absorption into the blood stream. Its exact nature is unknown. The pylorus is important in the origin of this humoral factor. It is similar to but does not seem to be histamine.

During the past six decades the scope of gastric surgery has been affected by two other factors in addition to the increasing knowledge of the physiology of the gastric secretion. The first is improved technique. The second is the increasing awareness of the relative effects of the complications compared with the total accrued benefits of gastric surgery in the ulcer patient. Excluding immediate postoperative complications such as a duodenal fistula, most of the late complications may be grouped under two heads. Mechanical difficulty and failure sufficiently to reduce gastric acidity. The former may be almost completely eliminated by proper technique. The latter factor has long been recognized as of first importance and has recently been reviewed by Wangensteen (83, 84, 32) and his colleagues. Yet the relation of acid and pepsin and its total combined effect is still unknown. The studies of Schiffmann (68) and Kolouch in this question are important. They noted that hydrochloric acid alone did not cause ulceration of isolated intestinal loops. However when combined with pepsin, ulceration always occurred. Nevertheless, peptic ulceration does not occur where there are low free acid values.

Following Edkins (20, 21) researches, pylorotomy was thought to be a satisfactory operation. Yet because of the incompleteness of resection of acid producing glands marginal

ulceration was common despite elimination of part of the gastric phase of digestion. Because of complications following incomplete closure of the duodenal stump in penetrating acute duodenal ulcers in proximity to the ampulla of Vater and common bile duct the pyloric exclusion operation was popularized by Finsterer though first described by Von Eiselsberg (80). There again resulted a higher incidence of marginal ulcers despite the fact that in many instances an adequate resection of the fundic glands had been carried out. Haberer (30, 31), Ogilvie, Druner, Fromme, Fuchs and Schur noted a higher incidence of marginal ulcers following the Finsterer type of exclusion operation. McKittrick, Allen (3), Lahey, Baker, Ogilvie and others have reported isolated and small groups of cases in which marginal jejunal ulcers have healed spontaneously after simple excision of the excluded pylorus. Moore and Allen (2) have described cases in which failures of vagotomy were due to the presence of the pyloric antrum. This may be an important observation in support of Babkin's (6) rebuttal of Uvnas' observations mentioned earlier. This has led many surgeons to consider excision of the pylorus and two-thirds to three quarters of the fundus as an essential in the satisfactory operation for the ulcer patient. Yet occasionally it is impossible to resect the pylorus as noted above. Druner describes the necessity for removing the mucosa of the excluded pylorus. Wangenstein (82) has reported a new technique for the excision of the mucosa of the pylorus that involves less blood loss. McKittrick has reported a two stage operation where the second stage is the excision of the pylorus after preliminary exclusion.

In the experimental study of the problems raised by the various types of gastric operations the experimental production of peptic ulcers in animals has been a necessity. This has been aided by two significant contributions. The first was the development of the Mann-Williamson (53) operation which short circuits the alkaline secretions of the duodenum and exposes a loop of jejunum directly to the unneutralized acid secretion of the stomach. The second has been the introduction of intramuscular histamine beeswax preparations by Code and Varco. Further review of the

experimental methods of peptic ulcer production is beyond the scope of this paper. Reviews on this subject may be found in the papers of Lannin, Wangenstein (84), Morton, McCann and DeBakey.

Recently we have seen in this clinic 4 patients who had previously had gastric operations with pyloric exclusion followed by a marginal ulcer. In 2 of these mere excision of the pylorus without any operation of the ulcer resulted in prompt healing. This led us to review the subject and to do the following experiments.

EXPERIMENTAL METHOD

The influence of the pyloric antrum has been carefully assayed by the use of isolated pyloric and fundic pouches by numerous investigators referred to previously. Few investigators, however, have assayed the rôle of the pyloric antrum by the incidence of marginal ulceration in the experimental animal. Its importance has been deduced for the most part by the general incidence of marginal ulceration following various types of gastric operations and anastomoses.

Two groups of 10 dogs were selected. The animals were mongrels averaging 35 pounds in weight. Their hemoglobin, red blood cell count, white blood cell count, nonprotein nitrogen and plasma proteins were checked before use. Under intravenous nembutal anesthesia a subtotal gastrectomy was performed in each dog with removal of approximately two-thirds of the stomach. An anterior Polya type of gastrojejunostomy was performed utilizing the shortest possible afferent loop to the anastomosis by severing the ligament of Treitz and mobilizing the duodenum. The method used and position of the afferent limb of the anastomosis is shown in Figures 1 and 2. In the first group of animals the pyloric antrum was excluded after the method of Finsterer and left intact. In the second group of dogs the pylorus was resected (Fig. 3). Silk technique was used throughout and No. 0000 silk was used for the mucosal sutures. All operations were performed by one of us (J. A. S.) thus assuring constancy of technique. Following operation dogs were allowed water *ad libitum*. The first day milk the second and third days

Fig. The duodenum, though not retroperitoneal, can be more completely mobilized by severing the layers of peritoneal reflection (ligament of Treitz), that extend into the right lower quadrant in the dog. A left paramedian incision as used.

milk and kennel diet combined the fourth and fifth days and a regular kennel diet supplemented with meat thereafter. This diet was kept constant throughout the entire length of the experiment. The animals were observed each day. Their behavior, appearance, appetite, and stools were noted. Daily weights were measured at a constant time. After a suitable control period when the weights had stabilized and when the dogs were normal in behavior, intramuscular injections of histamine in beeswax were given. This material was prepared after the method of Code and Varco and of Hay. Though the technique is quite simple, two points of importance arose in attempts to secure a homogeneous mixture. The first was the necessity of grinding the crystalline histamine-diphosphate sufficiently

fine in a mortar. The second was the proper maintenance of temperature while mixing the materials. Heating a small mortar in water to boiling temperature and carefully drying with prompt use thereafter was sufficient to maintain the proper temperature. The mixtures were frequently assayed by noting the acid response in gastric analyses from the experimental animals.

Sixty-five milligrams of histamine diphosphate were injected intramuscularly each day except Sunday in the sacrospinalis or thigh muscles. The sites of injection were alternated. Care was taken not to place the material subcutaneously as hard indurated areas of foreign body and chronic inflammatory reaction resulted. Except for occasional vomiting at the time of injection, no untoward reactions

TABLE I—DOGS WITH PYLORIC ANTRA EXCLUDED

Number	Control eight pounds	Weight 1 death pounds	Days of histamine	Pathological findings
45-26	3	20½	76	Healed marginal ulcer after excision of pyloric antrum
46-40	28	33½	70	No evidence of ulcer
46-73	44	34	3	7 3 cm. chronic ulcer distal to anastomosis
45-38	43½	33	3	5 0.5 cm. chronic ulcer
44-200	44½	33	38	4 1 cm. chronic ulcer with central perforation
45-35	40	3	66	Healed marginal ulcer after excision of pyloric antrum
44-203	47	28	60	3 3 cm. chronic ulcer No change after excision of pylorus
45-47	42	29	3	Two ulcers. Largest 3 5 cm.

46-43	43	26½	30	2 5 cm chronic ulcer

resulted from these injections. When the animals showed symptoms of an ulcer namely listlessness anorexia vomiting tarry stools and weight loss roentgenograms were taken of the gastrointestinal tract utilizing tetraiodophthalimidoethanol as the contrast substance. Its use has been previously reported (39). Following this the dogs were explored. In 3 dogs of the first group the pyloric antrum was resected when a marginal ulcer was noted on exploration. The remaining dogs were sacrificed and a complete postmortem examination performed. Dogs of the second group where ulcers did not occur were explored at intervals. A gastrotomy was performed if any question of ulcer arose by gross palpation of the gastroenterostomy. After a 6 to 8 week period of injection if no ulcer developed final exploration was carried out the histamine was discontinued and the dogs were used for other sacrifice experiments. At this later date postmortem examinations were always performed for any evidence of an old healed ulcer. No regular gastric analyses were carried out except in isolated dogs to check their acid secretion or to assay histamine preparations.

EXPERIMENTAL RESULTS

In the first series of 10 dogs with the pyloric antra excluded 9 (90%) developed marginal

Fig. 2 The relative position and shortness of the afferent limb of the gastrojejunostomy is shown

jejunal ulcers distal to the anastomotic line and always toward or in the first few centimeters of the efferent loop of the gastroenterostomy. Two of these ulcers are shown in Figures 4 and 5. The ulcers were chronic in appearance and they had rather shallow craters; they were hard indurated and did not tend to perforate.

Microscopically these ulcers are identical with those encountered in man under similar cir-

Fig. 3 A diagrammatic illustration of the operation performed in the 2 groups of dogs. The only difference in the 2 groups is the presence or absence of the pyloric antrum.

Fig. 4. Dog 45-38. Chronic marginal jejunal ulcer after 5 days of histamine-bernax injections. Note position in efferent limb of anastomosis. The pyloric antrum has been excluded.

Fig. 5. Dog 46-48. Chronic marginal ulcer after 30 days of histamine-bernax injections. The position is identical to that shown in Figure 4. The pyloric antrum has been excluded.

cumstances with a central zone of necrosis and granulation tissue, a surrounding area of acute and chronic inflammatory cell infiltration and a varying amount of fibrosis. The microscopic appearance of such an ulcer is reproduced in Figures 6 and 7. The location of these ulcers emphasizes the pathway and mechanical factors concerned with the route of the acid gastric secretion.

In the second group of 10 dogs 2 (20%) developed ulcers. These 2 dogs died of acute perforations early in the experiment without the formation of a chronic ulcer with its attendant gross and microscopic picture described above. One of these ulcers is shown in Figure 8. Most striking is the path of erosion of the gastric juice in the efferent limb.

Fig. 7. Dog 45-38. Typical picture of a chronic peptic ulcer with central necrosis and peripheral inflammatory cell infiltration and fibrosis. $\times 65$.

TABLE II—DOGS WITH PYLORIC ANTRA EXCISED

Number	Control weight pounds	Weight at death pounds	Days of life value	Pathological findings
46-32	35	27	46	N evidence of ulcer
46-128	3	3	4	N evidence of ulcer
46-1	3 1/2	20	4	N evidence of ulcer
46-78	46	43	45	No evidence of ulcer
47-4	50	34	54	N evidence of ulcer
46-9	5	30		Perforated ulcer with multiple acute erosions
47-60	25	5	40	N evidence of ulcer
47-48	30	5	48	N evidence of ulcer
47-15	5	7	9	Perforated ulcer with multiple acute erosions
47-57	45	40	50	No evidence of ulcer

In the second dog that perforated in this series a similar picture was noted of an acute ulcer that was unlike the chronic ulcerations seen in the animals with pyloric exclusion.

The weight curves of the animals were an accurate guide to the condition of the animal. All animals lost 10 to 15 per cent of their body weight before their weight became constant after gastrectomy. The weight varied somewhat according to the habits of the dog. If no ulcer developed there was relatively little weight change after the initial loss. This is illustrated in Figures 9 and 10.

Fig. 9. Dog 45-26. Weight chart showing postoperative loss and recovery, a precipitous loss with development of an ulcer and prompt weight recovery with healing of ulcer.

Fig. 8. Dog 4-15. Acute perforated marginal ulcer after 9 days histamine beeswax injection. Note the path of erosion with gastric content along the entire margin of the anastomosis and into the efferent limb. The pyloric antrum was excised.

Except for seasons of the year the experimental conditions and surgery of the two groups of animals were maintained identically. The only difference was the presence and absence of the pylorus. In 3 animals the pylorus was excised after an ulcer developed. In

Fig. 10. Dog 46-49. Weight chart of an animal that did not develop an ulcer. Note the contrast with the chart in Figure 9.

2 of these healing resulted. In the third no effect was noted after excision of the pylorus and the dog had a very large indurated ulcer at postmortem examination. All animals showed a dilatation of the remaining portion of their stomachs with dilatation of the jejunum at the region of the anastomosis. These stomachs could accommodate up to 500 cubic centimeters of liquid without vomiting. Silk suture material sometimes protruded from the suture line but was never related to the ulcer anatomically. This has also been encountered by other investigators (74, 17). Though there was no relation to the formation of an ulcer this finding suggests that very fine absorbable catgut is better material for the mucosal suture than silk.

DISCUSSION

In this group of experiments a direct pathological method was used to determine the effect of the pyloric antrum on the incidence of marginal ulceration in the dog. Conditions were maintained as identical as possible in both groups of animals. The results indicate that the pyloric antrum when excluded is responsible for a higher incidence (90%) of marginal peptic ulcers than when it is excised (20%) and that with pyloric exclusion the ulcers are chronic rather than acute. Incidental observations by other investigators in the course of different experiments confirm this conclusion. Steinberg (74) noted a 75 per cent incidence of marginal ulcers in dogs with the antra excluded. Fauley observed four marginal ulcers in a group of 12 dogs with pyloric exclusions. Dott and Lim noted an increased incidence of marginal ulceration under such circumstances. Masaki (55) using rabbits also noted an increased incidence of marginal ulcers with pyloric exclusions. McMaster and DeBailey using pyloric occlusions and gastroenterostomy of the Devine type noted a 6 per cent and 50 per cent incidence respectively of marginal peptic ulcers. These experiments are not comparable to the former group however as there had been no gastric resection and the pyloric exclusion was rather indefinite. The large group of clinical observations that implicate the pyloric antrum as a factor in marginal ulceration has been mentioned.

The experimental method may be questioned in that intramuscular histamine may be said to produce a maximal continuous response and therefore, the effect of any humoral factor of an intact pylorus would be negligible. This may be true particularly in consideration of the papers referred to where marginal ulcers were of higher incidence in animals with excluded pyloric antra without the use of histamine. However the incidence of marginal ulceration here with the use of histamine and pyloric antral exclusion is higher than in any other reported group of experimental animals. Furthermore it was felt that additional stimulation was necessary as a two-thirds gastric resection had been performed thus approximating the 75 per cent resection described by Wangenstein that protects the animal from a histamine ulcer. Another factor in this regard is the question of desensitization to histamine after a few weeks of daily injection. Thus the exact effect of histamine over a long period may be difficult to assay. It is interesting that peptic ulcers have been noted in man during histamine desensitization (McHardy).

Another factor of independent significance is the peptic response to histamine. Linderström and his associates have definitely shown that there is pepsin secreted by the pyloric glands though less than in the glands of the body of the stomach. With resection of most of the pepsin secreting area of the body of the stomach the smaller amounts secreted by the pylorus may be of relatively much greater importance in combining with the acid secreted by the remaining and hypertrophied fundus and body of the stomach to form a marginal peptic ulcer. Many observers feel that pepsin is definitely stimulated by histamine. Babkin (8) however questions this, and wonders if this apparent increase in pepsin secretion may not be due to a washing out of pepsin already present by increased gastric secretion. He states the same opinion and considers that pepsin secretion is under direct vagal control.

The weight curves of these animals are interesting as they represent the summation of the anabolic and catabolic processes as related to intake and output. Clinically this has been stressed recently by Varto (78, 79). No single weight in a dog is of significance nor in the

patient, as a 1 to 3 pound daily fluctuation may occur even though weights are measured at the same time. However the weight curve of several days, weeks or months may be and is of actually more value clinically than are many of the more elaborate laboratory tests. The charts previously shown are examples of this.

After review of much of the literature concerning the question of a gastric hormone and the physiological and surgical significance of the pyloric antrum one wonders why an excluded antrum increases the incidence of marginal ulcers. By exclusion the ordinary mechanical and chemical stimuli of the pylorus are removed with a certain decrease in the secretory response of the remaining stomach. On the other hand the stimulus to the pancreatic and biliary flow from the low pH and content of the normal stomach may be reduced by exclusion. This would result in a decreased flow of neutralizing duodenal content shown to be so important in the experimental work of DeBakey. Yet the use of a short afferent loop may expose the duodenum in a retrograde fashion to a fairly normal gastric secretion. The relation of pepsin to the total picture is not clear but as suggested it may be a deciding factor in the relative balance of exciting and neutralizing agents, namely if acid pepsin mixtures are necessary for the production of an ulcer the additional pepsin secreted by the excluded pyloric antrum may be a most important factor.

SUMMARY AND CONCLUSIONS

1. An attempt to assay the rôle of the pyloric antrum in the incidence of marginal peptic ulcers has been made.

2. The literature concerned with the physiology of gastric secretion and particularly with the gastric phase of secretion has been reviewed. The pertinent literature concerning clinical observations on the rôle of the pyloric antrum has been included.

3. Experimentally the problem was approached directly utilizing 2 groups of 10 dogs. A subtotal gastrectomy was performed in each dog with the removal of approximately two-thirds of the stomach. An anterior Polya gastrojejunostomy was performed utilizing the

shortest possible afferent loop to the anastomosis by severing the ligament of Treitz and mobilizing the duodenum. In one group the pyloric antrum was excluded and left intact. In the second group the pylorus was resected. After a 2 month postoperative interval the dogs were injected daily with histamine in beeswax. Their daily weights, behavior, appetite and stools were followed with abdominal exploration when indicated. The incidence of marginal ulcers of the 2 groups of dogs was compared. Nine of 10 dogs (90%) with pyloric antra excluded developed chronic marginal ulcers. Two of 10 dogs (20%) without pyloric antra developed acute perforating marginal ulcers.

4. It is felt that the pyloric antrum definitely contributes to the increased incidence of marginal peptic ulceration.

5. The pyloric antrum should always be removed either at the same operation or at a second operation.

6. The mechanism of the increased incidence of marginal ulceration through exclusion of the pyloric antrum though discussed is not understood.

MALROTATION OF THE COLON

DEVELOPMENTAL errors in rotation of the colon sometimes play an important rôle in abdominal surgery. Mild abnormalities in position which are quite common may not only be compatible with good health but may remain undiscovered for many years, only to be observed during a routine x ray examination or at the time of an exploratory operation. However when the caliber of the bowel has been compromised, as from a volvulus or adhesions one is confronted with a serious situation and operation is usually necessary for its relief. The underlying developmental error almost always involves the midgut and the classical picture is most often that of acute or chronic obstruction of the duodenum.

The basic factors in the normal process of bowel rotation have been admirably presented by several embryologists yet valuable contributions have been made from the clinical side by abdominal surgeons. We refer in particular to the writings of Frazer and Robbins of Lon-

don Norman Dott of Edinburgh, William E. Ladd and Robert Gross of Boston, McIntosh and Donovan of New York, Gardner and Hart of Duke University, Raymond and Dragstedt of Chicago, Isabella Forshall of Liverpool and Rosenblatt of Portland, Oregon. The essential features of the process may be summarized as follows. About the fifth week of fetal life when the rapidly growing liver is disproportionately large for the size of the abdominal cavity the midgut is pushed forward through the umbilical orifice and occupies a temporary position within the umbilical cord. While there over a period of about five weeks it undergoes a considerable change in length the afferent or prearterial portion (extending from the duodenum to the vitelline duct) increasing very rapidly while the efferent or postarterial portion (made up of terminal ileum ascending and two-thirds of the transverse colon) grows much more slowly. It undergoes also at the same time a rotation in a counterclockwise direction of about 180 degrees on its axis which is the superior mesenteric artery. This is known as the *first stage of rotation*.

During the *second stage of rotation* which is comparatively brief the entire midgut returns to the abdominal cavity and in so doing it continues the process of rotation to a full 270 degrees the jejunum entering the abdomen first and being followed in natural sequence by the loops of upper ileum as they pass behind the superior mesenteric artery from right to left and occupy their normal place in the left upper quadrant. As this rotation further progresses the lower coils of ileum come to be in the right lower quadrant, while the cecum and ascending colon swing forward in front of the

artery from left to right and gradually seek their normal place on the right side.

During the *third stage of rotation* which goes on slowly over a period of several months, the cecum slowly descends into the right iliac fossa, the ascending colon and descending colon become fused along the lateral gutters, the transverse mesocolon adheres to the lower part of the duodenum, the left transverse colon becomes somewhat stabilized by the gastrosplenic omentum while the sigmoid remains comparatively free. It is important to note that the root of the mesentery of the entire small bowel becomes firmly anchored along a broad oblique line from the left upper to the right lower quadrant.

It is easy to understand how any marked departure from this normal process of rotation and fixation might readily lead to serious trouble. If the midgut fails to return to the abdominal cavity and the child is born with it still protruding into the umbilical cord an *exomphalos* is present, a serious situation but one not incompatible with life if surgery is performed immediately after birth. If during the first stage the midgut fails to rotate at all and returns to the abdomen through the wide open umbilical orifice *en masse* so to speak a *non rotation* exists which in turn may either be followed by fixation of the bowel abnormally or because of a complete lack of fixation lead to a volvulus or twist of the entire midgut. If during the return of the midgut to the abdomen the rotation is in the clockwise direction with the cecum and ascending colon leading the way to pass under the artery from left to right, a *reversed rotation* has occurred which (though rare) when combined with lack of fusion may easily be followed by a twist of the midgut as great as 360 degrees. The term *malrotation* strictly speaking is that state of affairs that is present when either the normal counterclockwise rotation or the abnor-

mal clockwise rotation has been arrested before it is completed and one or more segments of bowel usually the cecum have become fixed by adhesions in an abnormal position.

From a *clinical* standpoint the end result is almost always an acute or chronic obstruction of the duodenum. Occasionally the onset of trouble is delayed for weeks, months, or even years and occasionally the onset is insidious with mild intermittent attacks of rhythmic abdominal pain, nausea and vomiting but in by far the majority of cases the picture is acute and comes on a few days after birth. The outstanding feature, of course, is the persistent vomiting of bile, and it is usually associated with fullness in the epigastrium and flatness of the lower belly. If however the obstruction is incomplete and intermittent in character the several loops of twisted midgut may contain much fluid and gas and a mass may be readily palpable. It must be remembered also that the twisted loops of bowel may be filled with venous blood and that if the neck of the volvulus is loose considerable of that blood may be passed by rectum. In making the diagnosis, the x ray film is sometimes of great help because a duodenum distended with air means obstruction in its lower part whereas the introduction of barium by Levine tube will clearly show the exact site and also the degree of narrowing. Air or barium when used from below are also of diagnostic value inasmuch as a normally filled colon speaks for an obstruction higher up and one that fills in its distal portion only gives one a strong clue that a volvulus of the midgut might be present.

Early surgery is the key to success and it consists essentially in untwisting a volvulus or completely severing abnormal adhesions associated with a malrotated colon. Through an ample incision the entire abdomen is explored

The distended duodenum is noticed at first glance and the absence of the colon in its normal place gives one an immediate clue as to the basic underlying pathology. Any adhesions or bands that bind the junction of the duodenum and jejunum are carefully divided until the normal caliber of the lumen is re-established, and a volvulus if present is slowly unwound and warm packs are applied until the congestion is relieved and normal color of the bowel returns. Gangrene fortunately is rarely present if operation is performed early and therefore resection is seldom necessary. Insurance against recurrence of obstruction is a difficult problem yet much may be accomplished in that direction by restoration of a malrotated gut to approximately its normal position and by fixing it there by properly inserted lines of sutures.

EDWIN M. MILLER

CONGENITAL HYDRONEPHROSIS AND HYDROURETER

ABOUT 12 per cent of all individuals are born with some variety of urogenital tract malformation and of these approximately one in six has congenital obstruction in the upper urinary tract. It is with this last group that we are here concerned as factors in the genesis of hydronephrosis and hydroureter. With the exception of certain instances of neuromuscular dysplasia congenital dilation of the renal pelvis or ureter or of both results from obstruction. Renal excretion begins between the fifth and sixth month of fetal life and for this reason when obstruction exists advanced hydronephrosis and other urinary backpressure damage often exists at birth.

Stricture is by far the commonest congenital urinary obstruction and may occur in one form or another at any point from the prepuce

to a renal calyx. This includes congenital contraction of the vesical outlet. Secondary ureteral kinks and an altered angle of ureteral insertion into the pelvis are frequent and may compound the obstruction. Aberrant renal vessels sometimes compress the ureter either primarily or secondarily and rarely aberrant uterine vessels block the lower ureter. Occasionally the ureter is compressed by congenital bands or ureteral diverticulum. Urinary calculi though sometimes present at birth are acquired and not congenital.

Hydronephrosis results from continued urinary obstruction and when the blockage is below the ureteropelvic level there is hydro-ureter as well. In the development of hydronephrosis the earliest gross pelvic changes are noted in the minor calyces. As the pelvis and calyces dilate the parenchyma is increasingly compressed against the resistant fibrous renal capsule and the volume of the vascular supply and particularly of the capillary bed of the organ is correspondingly reduced. Trophic changes in the parenchyma result from anoxemia and anemia and there is tubular dilation, progressive parenchymal thinning, atrophy, sclerosis and diminution of function. Unrelieved the organ becomes a large dilated sac capped by a thin sclerotic rim of parenchyma which is of little or no functional value. Yet in most instances renal infection intervenes—probably most often hematogenous—and the diagnosis chronic pyelitis too often satisfies the physician. The advent of infection accelerates the destructive process.

In the earlier stages of hydronephrosis the renal change—a compression nephritis—is a reversible one. Elimination of obstruction and co-existing infection is commonly followed by return to essentially normal kidney function. When the obstruction is unrelieved or persistent ravaging therapeutically resistant infection has the upper hand the renal change be-

comes irreversible and usually nephrectomy is demanded. The renal lesion is readily identified by complete urologic examination. Persistent pyuria or pain or tumor along the course of the upper urinary tract is the usual indication for this investigation. In some instances the pain may simulate intra abdominal disease such as cholecystitis, appendicitis, intestinal obstruction and so forth and lead to needless laparotomy. The foregoing merits grave consideration because in a fourth of the cases of congenital supravescical obstruction the lesion is bilateral.

Congenital ureteral stricture occurs most often at the pelvic junction. This as well as congenital stricture in other body systems such as the biliary and intestinal tracts is simply an anomalous narrowing of the lumen and without induration or fibrosis except as subsequent inflammation or infection has occurred. These strictures usually involve only a short section of the ureter not over two to three millimeters long but may be elongated to one two or more centimeters. Usually the correct diagnosis is readily made by complete urologic examination but in some cases only renal exploration will demonstrate whether the obstruction is due to stricture, aberrant vessel blockage at the pelvic outlet, ureteral compression by fibrous bands, enlarged lymph nodes or purulent collections. Treatment is preferably conservative by ureteropelvicoplasty when the renal damage is within limits of conservation. In our hands the Foley Schwartz ureteropelvicoplasty has been the most satisfactory and has been employed successfully even when the only kidney of young children was involved. In about half of the cases the obstructive damage and particularly the ravages of infection demand nephrectomy. When the kidney is the only one and ureteropelvicoplasty is technically impossible or impracticable we employ permanent nephrostomy.

Stricture below the ureteropelvic level occurs predominantly at the ureterovesical junction where it is bilateral in about a third of the cases. As a rule the dilation is greatest just above the stricture and this often acts as a buffer to spare the kidney the full harmful effects of the urinary backpressure. Where ureterorenal damage is not advanced stricture in the lower half of the ureter will usually respond satisfactorily to periodic progressive cystoscopic dilation with ureteral bougies. In dense ureterovesical junction stricture, cystoscopic division of the stricture or as the writer prefers transvesical incision through the open bladder and catheter intubation (No 12 to 14 F) for a week or so will promptly establish a widely patent channel through the stricture area. But successful operation to be thoroughly effective must be followed by periodic ureteral dilation sufficient to assure that free drainage exists. Plastic operations on the body of the ureter are generally unsatisfactory. When renal damage is therapeutically hopeless ureteronephrectomy is the procedure of choice and will be required in about 25 per cent of all cases of congenital stricture in the lower ureter of the young. All of the dilated ureter including the area of stricturation is excised with the kidney. When the opposite kidney is absent or will not support life and conservative treatment of the primary side is unsuccessful or offers an unjustified risk permanent nephrostomy is employed. Yet when the stricture is sufficiently distant from the kidney to permit a cutaneous ureterostomy will usually be more easily managed postoperatively.

Aberrant vascular obstruction commonly manifests itself in the young chiefly by persistent pyuria or pain in the side or both pyuria and pain. About 25 per cent of all kidneys have an anomalous blood supply with aberrant arteries, veins or both passing from

the upper pole, laterally from the cortex or downward or upward and medially from the lower pole. We are concerned here with the last group because they often cause primary or secondary obstruction of the upper ureter which they traverse. Transverse compression of the ureter by the anomalous vessel usually is urographically demonstrable and there is retention of opaque media above the obstruction. Yet the pyelogram as well as the clinical picture is sometimes indistinguishable from ureteropelvic junction stricture. In half of the cases of vascular ureteral blockage in children advanced renal damage requires nephrectomy. In the others compressing veins may be divided with impunity. If a compressing artery supplies more than a fourth of a kidney and therefore should not be cut, pelvicoplasty is done to alter the local anatomy sufficient to eliminate the obstruction. Anomalous vessels compressing the lower ureter are preferably divided; the alternative is ureteroneocystostomy or, with renal damage, ureteronephrectomy. MEREDITH F. CAMPBELL.

HYPOSPADIAS

SUCCESSFUL surgical correction of hypospadias should result in first, normal sexual function; second, a urethral channel of good caliber; third, a meatal opening that is at or very near the normal location of this opening in the glans penis.

It is a well recognized fact that the treatment of hypospadias is a peculiarly difficult problem. This was aptly phrased by Higgins who said, "Hypospadias is a grievous deformity which must ever move us to the highest surgical endeavor. The refashioning of the urethra offers a problem as formidable as any in the wide field of our art."

Many methods of surgical treatment have been described in the literature but no writer

has been willing to give a statistical analysis of a series of cases to show the percentage of good results obtained. The variety and number of operations proposed together with the lack of any analytic report of results would seem to indicate that surgeons concerned with the problem still are seeking a better solution of it.

In 1937 McIndoe¹ discussed the use of Edmunds' operation for correction of chordee, and also the use of an inlying tubular (or tunnel) graft for restoration of the missing portion of the urethral channel. The inlying tubular graft method for restoration of the urethral channel appears to offer the possibility of particularly gratifying results. There has come to our attention an as yet unpublished report of use of the method in 29 cases of major hypospadias during the past five years. Judged according to the criteria set forth in the opening paragraph of this editorial, good results were obtained in 27 cases; a fair result was secured in 1 case and there was only 1 failure. This is evidence of encouraging progress in the management of a most difficult problem.

Best results are obtained with the inlying tubular graft if the graft is not inserted until the patient has reached the age of about 16 years. Acceptance and use of this method of treatment will require a change in the attitude of many physicians regarding the age at which correction should be made. Many physicians argue that correction should be made when the patient is at an early age because of fear that the presence of the deformity will lead to psychic disturbances. Great pressure often is brought to bear by parents and others because of the same fear to have the surgeon undertake the correction when the patient is at an early age. Careful observation of a considerable number of boys at the age of puber-

¹McIndoe, A. H. *Am. J. Surg.*, 937:35, 176-185.

ty who had hypospadias and who had not had their deformity corrected did not reveal any with psychopathic tendencies. It would seem more reasonable to anticipate the possibility of a psychosis a little later when the patient may contemplate marriage. It is of course true that the necessity for delay of full correction until the patient is 16 years old will lead to definite difficulties with which the boy must contend before he reaches that age. When he is 10 or 12 years of age however he should be old enough to understand his prob-

lem and a frank discussion of it together with an explanation of the plans for correction at the proper time will enable him to manage his difficulties satisfactorily.

There is no contraindication to and there are some advantages in correction of chordee in childhood but the use of the inlying tubular graft should be deferred until the patient has attained the age of 16 years. If desired the whole program can be deferred until puberty without fear of disadvantage.

FRED Z. HAYES.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE *History of Medicine* by Cecelia C. Mettler¹ is actually fifteen histories of the scientific and medical specialties which compose the sum total of medical knowledge. In other words the history of anatomy from ancient times to the present is given in two sections. The history of physiology from the seventeenth century through the nineteenth century is given in another section and similarly pharmacology, pathology and bacteriology have their own chapters in the work.

The field of physical diagnosis is covered from the time of the medicine man to that of the present physical scientists. Following this medicine is taken up from the stages of development in the Assyrian and Egyptian periods down to modern times. Neurology and psychiatry then are studied from the pre-Grecian period through the nineteenth century. Venereology has a separate section. Dermatology is also set aside as is pediatrics.

Surgery has a long series of chapters beginning with a discussion of trephining as carried out in the primitive human society of the Cro-Magnon period and reaching down to the end of the nineteenth century. Obstetrics and gynecology, ophthalmology, and otology and rhinolaryngology each have their separate sections. The pages are filled with the names of the individual workers in all these specialties and each page contains numerous footnotes and references about them. Each chapter of each section ends with a series of selected readings giving not only modern references but a large list of reference works and texts. This is all incorporated in a single volume of a little over twelve hundred pages. This is thoroughly indexed both as to subject matter and as to personal names appearing in the text. Thus one may turn to the work to look up any individual physician or authority in the entire field of medicine and its allied sciences. One is impressed with the condensation of an immense amount of knowledge.

The book was edited by Professor Fred A. Mettler who says in his preface. It is one of the functions of the historian to preserve and explain the continuity of the present with the past. The greatest obstacle to medical progress and indeed to all cultures is the loss of this continuity with the past. Such a work as this certainly facilitates this continuity and enables one to learn easily of the work in almost any field in which he might be interested.

Many of the original classical authors in medicine are quoted extensively so that the work in this volume includes much of the original writings of the past. This adds to the realism and romance as well as providing precise information in regard to the earliest works. In the author's conclusion a sentiment is expressed with which the reviewer heartily concurs. The larger liberal and practical advantage to be derived from the study of the history of medicine are many and many of these will have become apparent to the student who has perused the preceding pages with care.

PAUL STARR

IN the second edition of his book on surgical disorders of the chest Dr. Donaldson² has done a remarkable piece of work in getting into the confines of this relatively small book a complete survey of the subject. Furthermore there are numerous references to work that has not yet been published. Thus the reader is brought the latest opinions available on a number of important subjects.

All of the conditions of the chest for which surgery can be used have been covered. The lessons learned in the recent war are discussed in some detail and their application to peacetime surgery emphasized.

There are certain sections of the book that are not clear especially that dealing with empyema. The author ignores the literal meaning of empyema and even discusses pyogenic empyema. Although he writes at considerable length about the pathogenesis of different types of empyema he has nothing to say about the manner in which localization occurs. In discussing non-purulent pure tuberculous empyema he misquotes Head and outlines the treatment of this condition as if it were a mixed infection.

The section on pericarditis is very good in so far as the consideration of the acute forms is concerned. He himself has made notable contributions to this subject. However in discussing chronic constrictive pericarditis he fails to make any reference to the pioneer work of Schmieden in Germany and of Beck and Churchill in this country. Also he fails to list increased venous pressure among the signs of the disease.

There are a number of other statements with which this reviewer would take issue. Among these are that bronchography by the direct injection of oil into the trachea should not be done and that, to know empyema is to know chest surgery. More upsetting

¹*SURGICAL DYSORDERS OF THE CHEST. DIAGNOSIS AND TREATMENT*. By J. K. Donaldson, B.S., M.D. F.A.C.S. 2nd ed. Philadelphia: Lea & Febiger 1947.

²*HISTORY OF MEDICINE. A CORRELATIVE TEXT, ARRANGED ACCORDING TO SUBJECTS*. By Cecelia C. Mettler A.B. Ed. B. A.M. Ph.D. Edited by Fred A. Mettler A.M. M.D. Ph.D. Philadelphia and Toronto: The Blakiston Co., 1947.

record of the medicine man the sweat houses the counterirritants and the medical and surgical practices of these primitive people. It is surprising to learn that the Indians added fifty-nine drugs to our pharmacopoeia that they successfully performed amputations using hot stones to control bleeding that they set fractures and sutured wounds. For all their superstitions and fetiches, one gets the impression that their patients often may have fared as well as those in the hands of the pioneer white physician with his rough and ready surgery his blood letting and his violent cathartics. Certainly the advent of the white man was no blessing to the Indian. With the whites came diseases which apparently were new to the Indian and to which he had relatively little immunity. Venereal disease measles scarlet fever tuberculosis and small pox were among these. In some of the early epidemics of small pox Indian tribes were decimated, and whole villages were depopulated.

In the next three chapters appears the story of medical men coming to Oregon with the Hudson's Bay Company, as missionaries to the Indians and as immigrants in the period of early American settlement. Towering among these figures is Dr. John McLoughlin, known to the Indians as the White Headed Eagle. Here too is the medical missionary Marcus Whitman, and the story of his death at the hands of the Indians he was trying to serve. The story includes a consideration of the factors which apparently led to the Whitman massacre. These first five chapters are the most interesting part of the book. An authoritative report has been woven into an absorbing story in which the whole history of medicine seems to be recapitulated.

Chapter six gives the history of medical men in each county of the State. Except for an occasional bright spot in which is described some individual doctor's peculiarities or some event in his practice this chapter is as unexciting as reading a dictionary. The last half of the book depicts the progress of medical education in Oregon. It tells of the development of a medical school medical societies and journals hospitals and institutions for the care of patients with communicable diseases. For the medical historian these chapters are a gold mine of exhaustive information. For the casual reader they are definitely hard reading. On the other hand, this section conveys something to the reader that is not immediately apparent. Hidden in the factual data and its careful documentation is the story of man's growing sense of his obligation to his fellow man. Whether the discussion deals with insanity tuberculosis or epidemic disease there is apparent a gradual recognition of the need for caring for the sick and protecting the well the acceptance of an obligation and the struggle to find the ways and means by which this obligation may be creditably discharged.

Dr. Larsell is imminently qualified to write this book. He grew up in the Pacific Northwest received his schooling in Oregon and his life work has been the teaching of medical students in that state. He

has always been interested in medical history and this book represents the culmination of a quarter of a century of devoted research. W. K. LIVINGSTON

THIS monograph *Ulcers of the Stomach and Duodenum* by Edmundo Vasconcelos of 125 pages and 154 illustrations is printed on excellent paper and with type large enough to be easily read. Many of the illustrations are truly superb.

The author knows this subject cannot be covered in detail in a monograph and states in the Foreword:

After twenty years of work in this field and having performed over 1000 operations for ulcer disease I have reached definite conclusions which I believe worth publishing. Since this book is exclusively intended to be presented at a meeting of specialists such as the 11th Congress of the International Society of Surgery (London 1937) all work and ideas already published as well as all the bibliographic quotations have been omitted. Its only aim is to establish the technical orientation of the author and must be strictly considered as a personal point of view.

It is obvious that Professor Vasconcelos has learned much from over 1000 surgical interventions for ulcer disease and that he has been influenced largely by the Continental school of surgeons particularly Austrian and German. American teachings publications and opinions have been of relatively minor importance. He has apparently pioneered and from experience learned which procedures survive the acid test of time these he has adopted and recommends.

The closure of the duodenum after a gastric resection by the double purse string method is therefore recommended though many American surgeons have found it hazardous and difficult. The anatomy of the upper gastrointestinal tract is carefully described and given a significant rôle in this text. The translation from Spanish to English is well done but nomenclature is occasionally confusing especially when used for instruments and surgical procedures having other names in English. Nothing new to the literature on surgical therapy for gastroduodenal ulcer is found in this text but surgical therapy advised by other authorities in this field and found satisfactory by the author merits repetition.

S. J. FOOLKSON

DESIGNED for the general practitioner Colwell's *Diabetes Mellitus in General Practice* is clearly written and up to date. Especially well presented are the early chapters on the general characteristics diagnosis and general treatment of diabetes. The method of diet calculation used by the author is described and in the chapter on insulin and its modifications his work with insulin mixtures is summarized. The book is recommended as a concise practical and readable discussion of diabetes mellitus.

CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

ARTHUR W ALLEN *Boston President*
DALLAS B PHEMISTER *Chicago President-Elect*

PRELIMINARY PROGRAM FOR 1948 CLINICAL CONGRESS THE BILTMORE HOTEL, LOS ANGELES OCTOBER 18 22 1948

THE thirty fourth Clinical Congress of the American College of Surgeons will convene in Los Angeles during the five days, October 18 to 22. The surgeons of that great city whose importance as a medical center is growing along with its spectacular increase in population are enthusiastically planning a comprehensive program of operative clinics and demonstrations to be held in local hospitals. Some of the operations will be telecast from the Los Angeles County General Hospital to a large room on the lower level of the Biltmore Hotel. The clinicians at some twenty five participating hospitals have arranged programs which will incorporate the latest advances in surgical technique and operative procedures. A preliminary schedule of the clinics demonstrations, and other presentations to be given at the hospitals appears in the following pages. These will be finally revised and amplified immediately preceding the Congress. A complete detailed program will be published each day for the succeeding day in the form of *Daily Bulletins* which will be distributed at the Headquarters hotel, The Biltmore.

The sessions at the Biltmore Hotel, the adjacent Biltmore Theater and the Philharmonic Auditorium across the street, will, like the clinics in the hospitals, include subjects in general surgery obstetrics and gynecology fractures orthopedic surgery, thoracic surgery neurosurgery genitourinary surgery and ophthalmology and otorhinolaryngology. Several official meetings are also scheduled. A series of Hospital Standardization conferences will be held for four days from Monday through Thursday. As stated previously telecasts of operations will be shown. There will be the usual impressive display of scientific and technical exhibits.

PRESIDENTIAL MEETING

The opening evening session of the Clinical Congress will be devoted to the Presidential Meeting at which the officers-elect, consisting of Dr Dallas B Phemister of Chicago as president Dr Howard A Patterson of New York as first vice president, and Dr Carl H McCaskey of Indianapolis as second vice president will be installed. Dr Arthur W Allen of Boston outgoing president and vice-chairman of the Board of Regents will preside and will deliver the Presidential Address. The third Martin Memorial Lecture will be delivered by Dr Clarence Crafoord, professor of surgery University of Stockholm. Dr Crafoord's subject will be Some Aspects of the Development of Intrathoracic Surgery.

The Annual Convocation will be held on the final evening Friday. The formal initiation ceremonies and the presentation of the Fellowship Address by Dr L. A. Du Bridge, president California Institute of Technology Pasadena will constitute the program. Dr Du Bridge's subject will be, The Physicist Meets the Doctor.

ASSEMBLY OF INITIATES

The 1948 initiates will attend an assembly on Friday afternoon from 1:30 to 2:15 o'clock in the Temple Baptist Church. Dr Dallas B Phemister incoming president of the College, will preside. Dr Irvin Abell chairman of the Board of Regents and Dr Bowman C. Crowell and Dr Malcolm T. MacEachern associate directors will briefly outline the program of the College.

OTHER OFFICIAL MEETINGS

The annual meeting of the Governors and Fellows of the College will be held on Thursday after

noon at 1 30 o'clock. Reports on activities of the American College of Surgeons will be presented by the officers and chairmen of the standing committees, followed by the election of officers.

Meetings of three important committees will be held on Wednesday as follows: State and Provincial Executive Committees, 9:00 to 10:00 a.m.; State and Provincial Credentials Committees and Committees on Applicants and Judiciary Committees, 10:00 to 11:00 a.m.; and National and Regional Fracture Committees, 3:30 to 5:00 p.m. The Committee on the Library will be held on Thursday from 3:00 to 4:00 p.m. A dinner for the Committee on Fractures and Other Traumas, and chairmen of the Regional Committees, will be held from 6:00 to 8:00 p.m. on Thursday.

FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

The Forum on Fundamental Surgical Problems, one of the most popular features of Clinical Congresses during the past few years, will be held on Tuesday through Friday, mornings, in two sections meeting concurrently. Brief reports of original clinical and experimental observations relating to the broad aspects of surgery and the surgical specialties will be presented under the general direction of Dr. Owen H. Wangensteen, chairman of the committee Forum on Fundamental Surgical Problems.

EVENING SCIENTIFIC SESSIONS— GENERAL SURGERY

"Malignant Lesions of the Thyroid Gland" will be the subject of the Tuesday evening general surgery symposium. "Histologic Types of Thyroid Carcinoma and their Clinical Significance," will be discussed by Dr. Frank W. Foote of New York, "Aberrant Thyroid," by Dr. Brien T. Kling of Seattle, "Malignancy in Nodular Goiter" by Dr. Warren H. Cole of Chicago and "Radioactive Iodine for the Treatment of Thyroid Disease Including Cancer" by Dr. Myron Primmett, Los Angeles.

"Endometriosis" will be the subject for the Wednesday evening general surgery symposium. "The Medical Treatment and Significance of Endometriosis," will be discussed by Dr. Joe V. Meigs of Boston. "Surgical Procedures Involved in the Treatment of Endometriosis," by Dr. Virgil S. Counsellor of Rochester, Minnesota and "Etiology of Endometriosis," by Dr. Brooks Ranney of Chicago. The annual Fracture Oration will also be presented at the Wednesday evening session.

"Surgery of the Heart and Great Vessels" will be the subject of the Thursday evening general surgery symposium. "Surgical Treatment of Pul-

monic Stenosis," will be discussed by Dr. Alfred Blalock of Baltimore. "The Surgical Treatment of Constrictive Pericarditis," by Dr. Emile F. Holman of San Francisco. "The Surgery of Patent Ductus Arteriosus," by Dr. John C. Jones of Los Angeles and "Treatment of Coarctation of the Aorta," by Dr. Robert E. Gross, Boston.

EVENING SCIENTIFIC SESSIONS—OPHTHALMOLOGY

The preliminary program for the Tuesday evening Ophthalmology session includes the following subjects: "Tumors of the Eyelids and the Conjunctiva" by Dr. Michael J. Hogan of San Francisco, "Partial Keratectomy," by Dr. George L. Kilgore of San Diego, and the Third paper will probably be on "Studies of the Cytology of Conjunctival Exudates."

The Wednesday evening program will be devoted to a panel discussion on the subject: "Neoplasms of the Eyelids, Orbit, Nose, and Accessory Sinuses—Treatment and Plastic Repair" and will be participated in jointly by ophthalmologists and otorhinolaryngologists. Dr. Gordon B. New of Rochester, Minnesota, will be the moderator.

The program for the Thursday evening Ophthalmology session includes the following subjects: "Retinal Detachment" by Dr. Dohrmann K. Puchel of San Francisco, "The Use of Retrobulbar Alcohol Injection for Ocular Pain" by Dr. Alfred E. Maumenee of Baltimore, and a third paper is not yet definitely selected.

EVENING SCIENTIFIC SESSIONS— OTORHINOLARYNGOLOGY

The preliminary program for the Tuesday evening Otorhinolaryngology session includes the following subjects: "Effects of Streptomycin on Eighth Nerve Function" by Dr. Page Northington of Oakland, "Anatomical Considerations in Ear Surgery" by Dr. J. Brown Farmer of Tampa, and "Chronic Laryngeal Stenosis," by Dr. John B. Erich of Rochester, Minnesota.

The Wednesday evening program will be devoted to a panel discussion on the subject: "Neoplasms of the Eyelids, Orbit, Nose and Accessory Sinuses—Treatment and Plastic Repair" and will be participated in jointly by ophthalmologists and otorhinolaryngologists. Dr. Gordon B. New of Rochester, Minnesota, will be the moderator.

The program for the Thursday evening Otorhinolaryngology session includes the following subjects: "Present Day Status of Fenestration Surgery" by Dr. Leighton F. Johnson of Boston, "Tumors of the Nasopharynx," by Dr. Harry C.

Rosenberger of Cleveland Modern Management of Oro-Antral Fistula by Dr Richard Thomas Barton of Beverly Hills and Surgical Treatment of Laryngeal Cancer by Dr Chevalier L. Jackson of Philadelphia

GENERAL SURGERY PANEL DISCUSSIONS

General surgery panel discussions will be held on Monday, Tuesday and Wednesday after noons, from 1:30 to 3:00 and from 3:30 to 5:00 o'clock and on Thursday afternoon from 3:30 to 5:00. The early session on Monday will be on Acute Renal Failure in Surgical Patients, with Dr Frederick A. Collier of Ann Arbor as moderator and the late session on Tumors of the Mouth, Jaw and Face, with Dr Gordon B. New of Rochester, Minnesota as the moderator. The early session on Tuesday will be on Low Lying Malignant Lesions of the Bowel with Dr Fred W. Rankin of Lexington, Kentucky as moderator and the late session on Evaluation of Liver Function in Relation to Surgery with Dr Nathan A. Womack, Iowa City as moderator. The early session on Wednesday will be on Peripheral Arterial Disease with Dr Alton Ochaner of New Orleans as moderator and at the late session 'Ulcerative Colitis' will be discussed, with Dr Henry W. Cave of New York as moderator. The Thursday session will be concerning Isotopes in Surgery with Dr George M. Curtis of Columbus as moderator.

OPHTHALMOLOGY PANEL DISCUSSIONS

Panel discussions in ophthalmology will be held Tuesday, Wednesday and Thursday mornings from 9:00 to 10:30 o'clock. The Tuesday subject will be Surgical Management of (1) Acute Inflammatory Glaucoma (2) Chronic Simple Glaucoma (3) Congenital Glaucoma, with Dr A. Ray Irvine of Los Angeles as the moderator. The Wednesday subject will be Congenital Cataract, with Dr Otto Barkan of San Francisco as moderator. The Thursday subject will be Surgery of the Oblique Muscles with Dr C. Allen Dickey of San Francisco as the moderator.

OTORHINOLARYNGOLOGY PANEL DISCUSSIONS

Panel discussions in otorhinolaryngology will be held Tuesday, Wednesday and Thursday mornings from 10:45 to 12:15 o'clock. The Tuesday subject will be 'Rehabilitation of the Hard of Hearing' with Dr Walter P. Work of San Francisco as moderator. The Wednesday subject will be 'The Preparation of the Surgical Patient and Postoperative Care' with Dr Colby Hall of Los Angeles as moderator. The Thursday subject for

discussion will be Diseases of the Esophagus with Dr Alden H. Miller of Los Angeles as moderator.

SPECIALTY PANEL DISCUSSIONS

Specialty panel discussions will be held on Friday afternoon from 1:30 to 3:00 and from 3:15 to 4:45 o'clock as follows:

Urology—Moderator DR. REED M. NESBIT, Ann Arbor

1:30 to 3:00 p.m.—Present Day Management of Urinary Tract Infections

3:15 to 4:45 p.m.—The Clinical Management of Branched Renal Calculi

Orthopedic Surgery—Moderator DR. JOHN C. WILSON, Los Angeles

1:30 to 3:00 p.m.—Mechanical Derangements of the Knee Joint

3:15 to 4:45 p.m.—Fractures about the Hip

Thoracic Surgery—Moderator DR. FRANK S. DOLLEY, Los Angeles

1:30 to 3:00 p.m.—Diagnosis and Surgical Treatment by Pulmonary Resection for Carcinoma, Bronchiectasis and Tuberculosis

3:15 to 4:45 p.m.—Surgery of the Esophagus

Plastic Surgery—Moderator DR. TRUMAN G. BLOCKER, JR., Galveston

1:30 to 3:00 p.m.—Congenital Facial Deformities

3:15 to 4:45 p.m.—Burn Contractures of the Extremities

Gynecology and Obstetrics—Moderator DR. JOHN C. BURCH, Nashville

1:30 to 3:00 p.m.—Hysterectomy: Physiological Considerations—Indications

3:15 to 4:45 p.m.—Hysterectomy: Technical Considerations—Complications

Neurological Surgery—Moderator DR. HOWARD C. NAFFZIOER, San Francisco

1:30 to 4:45 p.m.—Cerebral Angiography

a Anatomical Interpretations of Angiography

b Characteristic Patterns of Angiography in Brain Tumors

c Angiography of Circulatory Lesions and Their Treatment

d Technique and Materials

AFTERNOON SYMPOSIA

Symposia on Cancer Choices and Cancer Detection Centers, and on Fractures and Other Traumas, will be held in the Ballroom and in the Biltmore Theater respectively on Tuesday afternoon from 2:00 to 5:00 o'clock. A symposium

on Graduate Training in Surgery will be held in the Ballroom on Thursday afternoon from 3:00 to 5:00 o'clock.

HOSPITAL STANDARDIZATION CONFERENCES

The twenty-seventh annual Hospital Standardization Conference which is an integral part of the Clinical Congress, will provide an opportunity for thorough discussion of many problems incident to hospital care of the patient. The sessions will be of vital interest to members of medical staffs of hospitals, trustees, administrators, nurses, and other executive personnel. During the four day conference selected authorities from various fields of hospital work will participate in the program.

The conference will open at 10:00 a.m. on Monday, October 18, in the Ballroom of the Biltmore Hotel with a joint meeting for surgeons and hospital representatives. Among the subjects which will be discussed at this and later sessions will be: The Point Rating System of the American College of Surgeons, Professional Accounting—the Medical Audit, Utilization of Nurses, Aides, Planning, Organization, and Management of a Modern Admitting and Emergency Department, Administrative Aspects of the Early Ambulation of Patients, the Personality Factor in Hospital Management, Coordination of Activities of Doctors, Administrators, and Trustees, Organization and Work of the Surgical Committee, and Advantages of Having Medical Staff Offices in the Hospital.

An especially interesting type of session, inaugurated at last year's Clinical Congress in New York, will be a Forum on Fundamental Problems in Hospital Administration, conducted in a way similar to the Forum on Fundamental Surgical Problems—that is, recent graduates from schools of hospital administration, who are now doing administrative work, will submit abstracts on subjects of current interest from which will be chosen some ten or twelve speakers who will present the discussions.

COMMITTEE ON ARRANGEMENTS

The Committee on Arrangements for the Clinical Congress in Los Angeles has been well organized and is actively functioning. The membership follows:

General Committee

Donald G. Tollefson, M.D., F.A.C.S., *Chairman*
 Hugh T. Jones, M.D., F.A.C.S., *Vice-Chairman*
 Harold Lincoln Thompson, M.D., F.A.C.S., *Secretary*
Treasurer
 Gilbert J. Thomas, M.D., F.A.C.S., *Represent of the College*
 Vincent Avey, M.D., F.A.C.S.
 Ma. W. Bay, M.D., F.A.C.S.
 J. MacKenzie Brown, M.D., F.A.C.S.

Lawrence Chaffin, M.D., F.A.C.S.
 A. Ray Irvine, M.D., F.A.C.S.
 Maurice Kahn, M.D., F.A.C.S.
 W. E. MacPherson, M.D.
 B. O. Ranshoun, M.D.
 Louis J. Regan, M.D.
 Carl Rousche, M.D., F.A.C.S.
 Stafford Warren, M.D.

Committee for the Southern California Chapter

Ray B. McCarty, M.D., F.A.C.S., *Riverside*
 Meredith G. Beaver, M.D., F.A.C.S., *Redlands*
 Clarence E. Rees, M.D., F.A.C.S., *San Diego*
 Carl G. Johnson, M.D., F.A.C.S., *Long Beach*
 James H. Saint, M.D., F.A.C.S., *Santa Barbara*

Hospital Committee

The members of the hospital committee are listed on succeeding pages with the list of hospitals participating in the clinical program.

MEDICAL MOTION PICTURES

An appreciated feature of the Clinical Congress will again be the showing of medical motion pictures each day. The latest available pictures on surgery and related subjects will be presented. Special showings will be arranged of medical motion pictures in the fields of ophthalmology and otorhinolaryngology. Both sound and silent films will be shown, all of which will have been approved by the Committee on Motion Pictures. Some of the newer medical motion pictures now under production will be shown.

TECHNICAL AND SCIENTIFIC EXHIBITIONS

The Technical and Scientific Exhibits will occupy the Ballroom foyer, the Renaissance Room, and the Gallery of the Biltmore Hotel, according to present plans. Leading manufacturers of surgical instruments, x-ray apparatus, sterilizers, operating room lights, ligatures, dressings, hospital apparatus and supplies of all kinds, and pharmaceuticals, and publishers of medical books will be represented.

ENTERTAINMENT FOR VISITORS

The Committee on Arrangements is planning a most interesting program for the wives and other guests of Fellows who are attending the Clinical Congress. Among the events planned are a luncheon at Coconut Grove with a style show and other entertainment, tours to the Hollywood studios, to radio stations, to the Huntington Library, to Mount Wilson Observatory, to Griffith Park Observatory, and to the residential districts in which are situated the homes of motion picture stars.

A special registration desk will be provided for guests. A fee to cover the costs of the tours and

entertainment will be charged which will amount, according to the present estimate to \$10.00 for the four days beginning Tuesday morning. Since the committee in charge needs to determine in advance how many persons wish to be included in the various events, registration is desired by mail as soon as possible.

ADVANCE REGISTRATION

Surgeons who wish to attend the Congress should register in advance. Under a new plan advance registration will greatly expedite the procedure of registering.

No registration fee will be charged. Fellows whose dues are paid to December 31, 1947. For endorsed Junior and Senior Candidates the fee will be \$5.00. Non-Fellows who after individual consideration are permitted to register will pay a fee of \$10.00.

No registration fee will be required of intimates of the class of 1948.

HOTEL RESERVATIONS

It is desirable to make hotel reservations as early as possible because of the shortage of hotel rooms that prevails in Los Angeles as well as in other cities. In making these communications should be addressed to the Los Angeles Convention and Visitors Bureau care of the Los Angeles Chamber of Commerce stating that you will be attending the Clinical Congress of the American College of Surgeons. All hotel reservations for the Clinical Congress are to clear through this Bureau. No correspondence should be sent directly to the hotels. A form for reservations was enclosed in the letter recently sent to Fellows. Choice of hotels may be designated. The hotels in Los Angeles require a deposit in advance.

There follows the list of member hotels, Convention and Visitors Bureau, Los Angeles Chamber of Commerce.

CLINICAL CONGRESS PROGRAM IN BRIEF

Monday, October 18

- 8:00-12:00 Clinics and Demonstrations—Local Hospitals
- 10:00-12:30 General Assembly—Ballroom
- 1:30-3:00 Panel Discussion—Philharmonic Auditorium
- 2:00-4:00 Television Surgical Specialties—Foyer Biltmore Bowl (Lower Level)
- 2:00- 5:00 Clinics and Demonstrations—Local Hospitals
- 2:00- 5:00 Hospital Conference—Ballroom
- 2:00- 5:00 Surgical Film Exhibition (General)—Biltmore Theater
- 3:30- 5:00 Panel Discussion—Philharmonic Auditorium
- 8:15-10:30 Presidential Meeting—Philharmonic Auditorium

Tuesday, October 19

- 8:00-12:00 Clinics and Demonstrations—Local Hospitals
- 8:30-12:30 Forum on Fundamental Surgical Problems—Philharmonic Auditorium

- 8:30-12:30 Forum on Fundamental Surgical Problems—Ballroom
- 9:00-10:30 Panel Discussion Ophthalmology—Conference Room No. 1
- 9:30-12:30 Hospital Conference—Music Room
- 9:30-12:30 Surgical Film Exhibition (General)—Biltmore Theater
- 10:00-12:00 Television General Surgery—Foyer Biltmore Bowl
- 10:45-12:15 Panel Discussion—Otorhinolaryngology—Conference Room No. 1
- 1:30- 3:00 Panel Discussion—Philharmonic Auditorium
- 2:00- 4:00 Television Surgical Specialties—Foyer Biltmore Bowl
- 2:00- 4:00 Surgical Film Exhibition (E.E.N.T.)—Conference Room No. 1
- 2:00- 5:00 Hospital Standardization Conference—Music Room

- 2:00-5:00 Symposium on Cancer Clinics and Cancer Detection Centers—Ballroom
 3:00-5:00 Symposium on Fractures and Other Trauma—Biltmore Theater
 3:30-5:00 Panel Discussion—Philharmonic Auditorium
 7:00-8:00 Surgical Film Exhibition (E.E.N.T.)—Conference Room No. 5
 8:00-9:30 Hospital Conference—Music Room
 8:00-9:30 Scientific Session—General Surgery—Philharmonic Auditorium
 8:00-9:30 Scientific Session—Ophthalmology—Conference Room No. 5
 8:00-9:00 Scientific Session—Otorhinolaryngology—Conference Room No. 5

Wednesday October 2

- 8:00-9:00 Meeting of Cancer Committee—Conference Room No. 6
 8:00-9:00 Clinics and Demonstrations—Local Hospitals
 8:30-9:30 Forum on Fundamental Surgical Problems—Ballroom
 8:30-9:30 Forum on Fundamental Surgical Problems—Philharmonic Auditorium
 9:00-9:30 Panel Discussion—Ophthalmology—Conference Room No. 5
 9:00-9:30 State and Provincial Executive Committees—Engineers Club
 9:30-9:30 Hospital Conference—Music Room
 9:30-9:30 Surgical Film Exhibition (General)—Biltmore Theater

- 9:00-12:00. *Plastic Surgery* Operative Clinic Selected cases. ARTHUR E. SMITH.

- 10:00-12:00. *Tumor Surgery* Nonoperative Clinic Thyroid Malignancy HENRY J. LANGZ.
- 10:30-12:00. *Tumor Surgery* Nonoperative Clinic Struma Lymphomatosa and Fibrosis. ROBERT C. SURRIDGE.
- 11:00-12:00. *General Surgery* Nonoperative Clinic Obstructive Corrosive Gastritis. LOUIS C. BENNETT.

Thursday

- 9:00-11:00. *General Surgery* Operative Clinic Selected cases. E. VINCENT ASKEY.
- 9:00-11:00. *Otolaryngology* Operative Clinic Selected cases. JOSEPH B. STEVENS.
- 9:00-12:00. *Gynecology* Operative Clinic Selected cases. BERNARD J. HANLEY JOHN C. McDERMOTT.
- 9:00-12:00. *Proctology* Operative Clinic Surgery of Colon WILLIAM H. DANIEL.
- 9:00-12:00. *General Surgery* Operative Clinic Vagus Neurectomy EDWARD C. PALLETT.
- 9:00-12:00. *Ophthalmology* Operative Clinic Selected cases. CLARENCE H. ALBAUGH.
- 10:00-12:00. *Orthopedic Surgery* Nonoperative Clinic Surgery of Hand. FRANK J. BREKLIN.
- 10:30-12:00. *Orthopedic Surgery* Nonoperative Clinic Surgery of Knee Joint. HUGH T. JONES, JOHN R. BLACK.
- 11:00-12:00. *Neurosurgery* Nonoperative Clinic Surgical Management of Intracranial Aneurysms—motion picture and lantern slide illustrations.
- 11:00-12:00. *General Surgery* Operative Clinic Selected cases. E. ERIC LARSON.

Friday

- 9:00-11:00. *General Surgery* Operative Clinic Selected cases. LOUIS C. BENNETT.
- 9:00-11:00. *Plastic Surgery* Operative Clinic Selected cases. ARTHUR E. SMITH.
- 9:00-12:00. *General Surgery* Operative Clinic Selected cases. FRANCIS E. BROWN HENRY J. LANGZ.
- 9:00-12:00. *General Surgery* Operative Clinic Selected cases. Wm. P. KROGER, ROBERT C. SURRIDGE.
- 9:00-12:00. *Genitourinary Surgery* Operative Clinic Selected cases. A. J. SCHOLL, E. CROWLEY.
- 10:00-12:00. *General Surgery* Nonoperative Clinic Thoracic Vagus Neurectomy—motion picture EDWARD C. PALLETT.
- 10:30-12:00. *General Surgery* Nonoperative Clinic Surgery of Spleen. RALPH V. BYRNE.
- 11:00-12:00. *General Surgery* Nonoperative Clinic Carcinoma of Tongue, or Primary Mandibular Tumors. IAN MACDONALD LEWIS GUTS.
- 11:00-12:00. *General Surgery* Operative Clinic Selected cases. DAVID A. SCHMIDT.

SANTA FE COAST LINES HOSPITAL,
LOS ANGELES

Monday

- 9:00-11:00. *Genitourinary Surgery* Operative Clinic Retropubic Prostatectomy V. J. GALLAGHER.
- 9:00-10:00. *Neurosurgery* Nonoperative Clinic The Herniated Intervertebral Disc Discussion of Multiple Herniations. HENRY M. CUNEO.
- 9:00-10:00. *Otolaryngology* Nonoperative Clinic Allergy of the Nose and Paranasal Sinuses. GORDON J. MCCURDY.

THE SANTA MONICA HOSPITAL

Thursday

- 9:00-11:00. *General Surgery* Nonoperative Clinics

Traumatic Surgery C. A. LINDQVIST
A New Method for the Movement of Fluids in the F
tremities. J. P. SAMPSON and FREDERICK G. KIRBY
Orthopedic Surgery Operative Clinics
Reconstructive Orthoplasty of Congenitally Dislocated
Hip. WILLIAM H. WRIGHT
Demonstration Pre-ambulatory Diagram of Dislocated
Hips. JOSEPH RISSNER
Contrast Orthogram of Dislocated Hips. RALPH
MILLER

U. S. ARMY MCCORNICK GENERAL HOSPITAL, PASADENA

Friday

9:00-9:30. *Genitourinary Surgery* Nonoperative Clinic
Amicrobial Urinary Infections. LYMAN STEWART
9:30-10:00. *General Surgery* Nonoperative Clinic
The Treatment of Regional Ileitis. GORDON K. SMITH
10:00-10:30. *Plastic Surgery* Nonoperative Clinic
Treatment of Facial Injuries. MORRIS K. RYAN
10:30-11:00. *Orthopedic Surgery* Nonoperative Clinic
Treatment of Fracture of Forearm. VERNON LOCK
11:00-11:30. *General Surgery* Nonoperative Clinic Hernia
Repair Using Cooper Ligament. LAWRENCE C. BULL

U. S. NAVAL HOSPITAL, LONG BEACH

Tuesday

9:00-10:00. *General Surgery* Operative Clinics Gastrec
tomy. E. F. LARSON Cholecystectomy. L. L. HAYS
Genitourinary Surgery Operative Clinics
Retro Pubic Prostatectomy. CARL RUSCHKE
Varicocelectomy. MILLO ELLER and L. A. NEWTON
Orthopedic Surgery Operative Clinic
Operation for Recurrent Dislocation of the Shoulder

COLLECTIVE REVIEW

- The Early Treatment and Results Thereof of Injuries to the Colon and Rectum With 70 Additional Cases. EDMUND R. TAYLOR, M.D. Rochester Minnesota and JAMES E. THOMPSON, M.D. F.A.C.S. New York New York 105

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

Head

- Contribution to the Study of Salivary Neoplasms. P. DESAIVE and J. DUCKERT 123
Diseases of the Salivary Glands. A. C. FURSTENBERG 123

Eye

- A Cross-Sectional View of Injuries to an Ophthalmic Practice in Elre. EUPHRAS MAXWELL 124
Peripheral Positional Nystagmus. P. G. GERLENG 124
The Surgical Treatment of Pterygium. ARTHUR D. OKERMAN 125
Lid Repair and Reconstruction. SIDNEY A. FOX 126
Statistical Study of Retinal Detachment. CECIL H. BAILEY 126
Saline Injections in Retinal Detachment. EDWIN G. GRAFTON, JR., and JACK S. GUYTON 127

Ear

- "Permanent" Deafness Due to Gunfire. G. REID 128
Foreign Body in the Eustachian Tube. Report of a Case. ROBERT C. McNAUGHT 128
Some Experiences in the Surgery of Labyrinthitis. PHILIP READING. 128

Nose and Sinuses

- Plastic Repair of the Obstructing Nasal Septum. SAMUEL FOMON, JOSEPH G. GILBERT, A. GILBERT SILVER, and VICTOR ROYCE SYRACUSE. 128

Pharynx

- Juvenile Nasopharyngeal Angioblastoma. HAYES MARTIN, HARRY E. ENGLISH, and JULES C. ABELS 129

Neck

- Tuberculous Cervical Adenitis. HAMILTON BAILEY 129
Complementary Extirpation of Lymph Glands. Critical Study. Indications and Technique. ALVARO RODRIGUES 130
Carotid Body Tumors. WILLIAM S. MACCOMBS 131
Gastric Acidity in Thyrotoxicosis. JUAN C. PLÁ, C. MUÑOZ MONTREVARO, and DANIEL MURGÚA 131

- Results of Prolonged Medical Treatment of Hyperthyroidism with Thiouracil. T. S. DANOWSKI, F. B. MAN, J. R. ELKINGTON, J. P. PETERS, and A. W. WINKLER 131

- Lingual Gout. EMIL GORTSCH 132

SURGERY OF THE NERVOUS SYSTEM

Brain and Its Coverings. Cranial Nerves

- Experimental Observations in the Treatment of Craniostenosis. FRANCIS D. INGRAHAM, DONALD D. MATSON, and EBEN ALEXANDER, JR. 133
Cerebral Arteriography. I. S. WECHSLER and S. W. GROSS 133
Herniation of the Cerebral Ventricles. CHARLES R. PERRYMAN and EUGENE P. PENDERGRASS 133
Observations upon Patients with Penetrating Wounds Involving the Cerebellum. JOHN E. WEBSTER, R. C. SCHNEIDER, and J. E. LOFSTROM 134
Medulloblastoma Cerebelli. FRANCIS D. INGRAHAM, ORVILLE T. BAILEY, and WILEY F. BARKER 135
Postoperative Period of Survival of Patients with Oligodendroglioma of the Brain. Report of 25 Cases. HENRY A. SHEKIN, FRANCIS C. GRANT, and JOHN H. DREW 135

Spinal Cord and Its Coverings

- The Occurrence of Extensor Spasm in Patients with Complete Transection of the Spinal Cord. MARTIN B. MACHET and ROBERT A. KUHN 136
Skeletal Traction and Anterior Decompression in the Management of Pott's Paraplegia. NORMAN M. DOTT 136

Peripheral Nerves

- Tantalum Foli Cuffs in Peripheral Nerve Surgery. EUGENE E. CLIFFTON 136
Concerning Surgical Treatment of Traumatic Injury to the Upper Division of the Brachial Plexus (Erb's Type). ALEXANDER LURJE 137

Sympathetic Nerves

- Juxta Adrenal Paraganglioma (Pheochromocytoma) with Hypertension Operated on Successfully. Disturbances of Glycoregulation in Paroxysmal Hypertension. R. FOYTAINE and J. WARTER 138

COLLECTIVE REVIEW

THE EARLY TREATMENT, AND RESULTS THEREOF, OF INJURIES OF THE COLON AND RECTUM

With 70 Additional Cases

EDMUND R. TAYLOR, M D Chapel Hill, North Carolina, and JAMES E. THOMPSON M D
New York, New York

THE average report of any large series of cases results largely from the study of records and histories. Rarely is there the added advantage of personal observation and intimate knowledge of each patient concerned. The recent war enabled us to utilize such an advantage. It is hoped that a report of this nature may be as revealing on the basis of the intimacy of contact with each patient, as a larger series assembled solely on the basis of records.

The essential part of this article is constituted by the ideas arising from the accumulated experiences of the Ninth Evacuation Hospital¹ to which more than 51,000 patients were admitted while the hospital was operating in North Africa, Sicily Italy southern France, and Germany. The 70 cases of injury to the large bowel which we are presenting in considerable detail represent all patients with such injuries admitted to our hospital without having undergone any previous surgical treatment. These patients were brought to our hospital while we followed the American advances from the shores of southern France into the heart of Bavaria. This 10 month period includes late 1944 and extends well into 1945.

In addition, the literature on wounds of the large intestine through 1945 (and some articles in English published in 1946 and 1947) was reviewed, most emphasis being placed on the period since

¹The Roosevelt Hospital Unit of New York City

1916. The French German Russian Italian and Chinese literature was reviewed, but no contributions of importance were found in it. It was found that the important advances have come from the British and Americans and mostly the British. The significant ideas and data found in this survey are presented together with our own data and experiences. Because the early and late phases of treatment are so intimately related to each other and to the final result we have included a brief consideration of the late phase of treatment and of the results to clarify the problem as a whole. Only in this way can the early surgical treatment be intelligently carried out.

Patients who had penetrating wounds of the abdomen were partially screened from this hospital by the surgeons working in the field hospitals. This screening was rarely complete, and under ideal circumstances only those men in good condition were allowed to reach us. There were many occasions on which the casualties were so heavy that the field hospitals were unable to cope with all the men with serious abdominal wounds, and had to evacuate them to us untreated. Men in this group comprised a large proportion of our patients, and the added factor of time and a prolonged ride in an ambulance made the outcome less favorable. This is mentioned to point out the fact that the condition of some of these men was the same as that of desperately ill men whom one would expect to find in a field hospital.

All our patients with abdominal wounds were taken to the shock ward immediately where they received preferential treatment. The rate of admission varied considerably. On one occasion surgical abdominal exploration was carried out 8 times during a 31 hour period. For 7 of these patients some form of colostomy was performed for injury to the large bowel. In another period 11 men with extensive injuries to the bowel were treated during the course of 6 days. In contrast to this, weeks might elapse without the occasion for surgical care for a single man.

Evacuation of these patients never was accomplished before the eighth postoperative day except in rare instances at the demand of the tactical situation. Fortunately none of these few patients were considered to be in such critical condition that they were likely to be harmed by travel.

The evacuation system from one hospital to another within the theater made it almost impossible to obtain data on the ultimate outcome of our patients. Therefore the main purpose of this article is to present the early results of injuries to the large bowel in their relationship to the extent of damage and the treatment accorded. Conclusions will be drawn which are felt justifiable on the basis of the data presented.

The types of missile which caused these injuries were divided equally between shell fragments and bullets. There were no instances of injury by blast, and no injury was caused by sharp instruments such as knives or bayonets. The causation in 2 cases was blunt force to the abdominal wall sustained in an automobile accident. One of these 2 patients exhibited in addition extensive lacerations in the mesentery of the ileum with sufficient damage of the circulation to have caused gangrene of two loops of the small bowel.

The average soldier possessed accurate knowledge as to whether he had been hit by a shell fragment, bomb fragment, or a bullet. However one could not expect him to be so dependable in de-

scribing the type of shell which had exploded in his neighborhood. The fear and respect accorded the German 88 mm gun gave many soldiers the fantastic impression that it was being used against them individually. The unreliable information on this score made it useless to attempt any further classification of shell fragments for instance, fragments of mortar shells or grenades. There seemed to be very little difference from the point of view of prognosis, whether the causative agent was a shell fragment or a bullet. Each one could be as devastating as the other. Men with wounds caused by massive shell fragments evidently die early for only one man so injured was seen in this hospital. He had sustained extensive injuries and died shortly after operation. His abdominal injuries were confined to the small intestine, and for this reason a description of the pathologic situation is not contained in the present article.

A survey of all the penetrating abdominal wounds during the period under consideration has shown that roughly half of them caused damage to the large bowel. The damage varied from transection and extensive laceration to small punctate wounds, abrasions, and contusions of the wall of the gut.

DIAGNOSIS

Too much stress cannot be placed on the importance of diagnosis in the treatment of penetrating wounds of the abdomen. The advances made in abdominal surgery are considerable, but the postoperative mortality rate in this type of war injury still occupies the unenviable position of being the highest. One important factor in the reduction of this rate is shortening of the interval between injury and operation (Table I). The surgeon is always able to influence this time factor favorably in one respect namely early prompt diagnosis.

In a previous study of 66 of our cases of penetrating abdominal wounds, it was found that surgical exploration with negative results had been performed on 14 occasions without death resulting from the procedure. This seemed a rather high incidence of surgical exploration with negative results, but on the other hand there was real compensation in the knowledge that there were no deaths resulting from failure to operate because of a missed diagnosis. It has always seemed safer to work on the hypothesis that if doubt exists, operation should be carried out, and this applies more strongly to injuries of the colon than to most other acute surgical conditions in the abdomen.

It is rarely possible to do more than to postulate that the large bowel has been injured. Whether or not the large bowel has been damaged is of sec-

TABLE I — THE TIME LAG BETWEEN WOUNDING AND OPERATION IN RELATION TO MORTALITY RATE: 110 CASES (JARVIS BYERS AND PLATT)

6 to	54	
to 12	36	30
12		30
Over		100

ondary importance to the decision that the abdomen must be opened but the large bowel was always considered to be the probable location of damage because of the need to plan the proper incision. In rectal injuries a positive knowledge of the site of injury is very important for if the injury is limited to the extraperitoneal portion of the rectum the abdominal operation can be confined to a McBurney type of colostomy as was performed in case 56.

Extraperitoneal wounds of the bowel very easily may escape undetected, unless they are expected in relation to the primary wounds and are carefully eliminated as a possibility. The peritoneal cavity may present a completely clean appearance with no damage otherwise to important structures. Search of the suspected region nearly always will disclose some degree of retroperitoneal extravasation of blood. The mobilized gut, when it is inspected for damage does not exhibit changes as readily over its unperitonealized surfaces so that great care must be exercised to insure detection of small, punctate wounds. Extraperitoneal injuries of the rectum do not lend themselves so readily to direct inspection from within the abdomen, nor is this necessary or desirable. Missiles which enter through the buttock, perineum and thigh can produce the same kind of injury, limited to that portion of the rectum not covered by peritoneum.

We found no new aids to diagnosis. The same reliance was placed on judgment and physical observations that is employed in the diagnosis of any acute condition of the abdomen. Great care was taken to examine the thorax thoroughly because of the possibility that the abdomen had been penetrated through the diaphragm. The frequency of occurrence of abdominal splinting in wounds completely confined to the thorax emphasized the importance of the roentgenogram in the localization of shell fragments or bullets, and in helping to plot the course of such missiles. It was found dangerous to rely too greatly on one's ability to outline the course a missile had taken because the position of the victim's body at the time he is hit can drastically change the path the missile will follow. Case 15 illustrates this feature: the patient in this case would have been operated upon much earlier and would have been saved a long ride in the ambulance, if the surgeon in the field hospital had not made the mistake of assuming that no abdominal viscera had been penetrated.

The buttocks, perineum and anus were carefully inspected, because the largest proportion of injuries to the rectum occurred after wounds had been inflicted in these regions. Digital examina-

tion of the rectum was very helpful in the detection of wounds of the anus or those situated low in the rectum and in the demonstration of blood in the feces. In addition proctoscopic examination should be performed for in several instances proctoscopy disclosed small penetrations of the rectal wall which might otherwise have been undetected.

PREOPERATIVE CARE

The preoperative care was concerned mainly with the treatment of shock. A unit of plasma was administered after blood for typing and cross-matching had been taken. Sometimes 2 but rarely 3 units of plasma were given. In general our experience seemed to indicate that neither plasma nor isotonic solution of sodium chloride could take the place of blood in combating the shock and that the administration of plasma was essentially a temporary measure used while blood was being obtained. The degree of shock varied considerably but even those patients who did not seem to be in shock received at least 1 unit of blood in most cases preoperatively. The hematocrit reading was taken routinely at the time of cross-matching but we found it much more practical to rely on the blood pressure, pulse rate, and general appearance of the patient.

No hard and fast rule was followed in the use of a definite value for blood pressure or pulse rate to indicate that the patient had reached the optimal time for operation. The rapidity with which the systolic blood pressure rose to and above 80 mm. of mercury consistent with a pulse which became less rapid and of good quality was a favorable sign. The stability attained at this level of improvement was even more important. The patient who relapsed into shock upon being moved no matter how slightly always constituted a poor risk.

In general a systolic blood pressure of 80 mm. of mercury or more was considered desirable before the patient was moved to the operating room but there were occasions when this level was never reached. In a great majority of cases the systolic blood pressure was more than 100 before the patient was moved to the operating room.

The amount of blood transfused preoperatively varied anywhere from 500 to 2500 c.c. When the condition of the patient was more serious the rapid transfusion of blood was very helpful and the blood was transfused under pressure. At times 2 units were transfused simultaneously. In the presence of venous collapse the ordinary indirect gravity method of administration even with the blood under pressure in the Baxter bottle did not

produce an adequate flow. A two-way stopcock can be interposed between the bottle and the vein in these cases, and the blood can be injected by means of a syringe.

The patients with thoracoabdominal injuries required special attention. The added disturbance to the thoracic mechanics increased the distress of the patient and aggravated the state of shock. If the injury was simple hemopneumothorax with out much damage to the lungs and no tension, aspiration of air and blood from the pleural cavity greatly improved the picture. Sucking wounds were temporarily controlled with an occlusive dressing. In the presence of tension pneumothorax, a catheter was placed in the second interspace anteriorly and negative pressure was maintained by attachment of the catheter to a tube placed under water. Thoracic pain was either relieved or controlled by intercostal nerve block, repeated at intervals if necessary. The aspiration of blood and mucus into the bronchial tree was a frequent occurrence, and unless they were removed, they delayed all efforts to improve the thoracic situation. Blood and mucus would accumulate not only on the side on which damage to the lung occurred but frequently on the opposite side. This feature presents a distinct operative hazard, because the patient must be turned on the side which is not injured when the operation on the thorax is being carried out, an action which diverts additional intrabronchial fluid to the lung which is carrying the main load. Early in our experience we lost several patients with thoracic injuries because of failure to realize the importance of obtaining a relatively dry bronchial tree before we proceeded with the operation.

The removal of these secretions was satisfactorily accomplished with the least disturbance to the patient by means of a catheter inserted into the trachea, through either the nose or the mouth, with the application of suction. Oxygen was administered by means of either an intranasal catheter or a mask, according to which method was tolerated the best.

Once the thoracic mechanics were controlled, either the patient was kept flat or his head and chest were placed in a slightly elevated position. In spite of the fact that the Trendelenburg position will demonstrably improve shock as manifested by small increases in the blood pressure, this position was rarely used in the cases of abdominal injuries. There was always the fear of extension of the upper abdominal and subdiaphragmatic spread of peritoneal soiling, moreover, those patients who had thoracic involvement did not breathe as easily in this position as in others.

It was often necessary to compromise between a thorough examination and what must be termed an adequate examination while the patient was in shock. Our patients were never moved off the litter from the time of admission until they were anesthetized on the operating room table, except under rare circumstances. The danger attendant on moving them too much even while they were on the litter made a meticulous physical examination impossible until their condition improved, but attention was always directed to the recognition and remedy of factors which would tend to prolong shock. This applied particularly to the proper splinting of fractures and attention to hemorrhage from wounds.

The bladder was always catheterized for diagnostic purposes. Catheterization not only provided valuable information as to probable injury of the genitourinary tract, but also insured an empty bladder which meant that abdominal signs could be more clearly evaluated. A duodenal tube was placed in the stomach preoperatively in some cases. In others, it was inserted before closure of the abdomen or just before the patient was returned to the ward.

After the necessary roentgenograms had been taken, and if the patient's condition permitted, he was sent to the operating room, usually with blood still running into his vein, and with 3 or more units crossmatched and carried by the litter bearers.

IMPORTANT FACTORS IN THE PROGNOSIS AND TREATMENT

Multiplicity of wounds. Extra abdominal wounds.—Many of our patients had multiple wounds situated elsewhere in the body but in only 2 (cases 66 and 69) could death be attributed to these wounds. One man (case 66) had an additional penetrating wound of the head, with extensive damage to the brain which in itself might have been fatal. Needless to say this does not minimize the important effect that multiple wounds may add to the traumatic shock or the hazards to be encountered if they are forgotten or inadequately treated. This recalls an instance in which a desperately ill patient had been treated for severe abdominal injuries in a field hospital. A penetrating wound of the knee joint had been inadequately treated, and a large foreign body had been allowed to remain in the joint. Suppurative arthritis then developed, and the destroyed joint later was resected to overcome sepsis.

Involvement of the spinal cord or cauda equina was seen 6 times in our series. Four of the patients died, which indicated that this combination of wounds is of most serious importance, and is a

TABLE II.—MORTALITY RATES IN WOUNDS OF THE LARGE INTESTINE WITH WOUNDS OF OTHER ABDOMINAL VISCERA VERSUS THOSE IN WOUNDS OF THE LARGE INTESTINE ALONE, IN CASES IN WHICH OPERATION WAS PERFORMED

Series and organs involved	Cases	Deaths

Series of Porritt			
Colon alone	77		1
Colon combined with other viscera	63		60

combination that should be approached with great caution.

The combination of thoracic and abdominal wounds with penetration of the diaphragm occurred in 6 cases, and in 3 of these the patients died.

Intra-abdominal wounds.—Agreement on the point that wounds of multiple abdominal organs increase the mortality rate associated with wounds of the large bowel is so nearly unanimous that little space need be given to the subject. Our figures in this respect are seen in Table II in the same table are some interesting figures cited by Porritt from the British and Canadian 21st Army Group in World War II. Porritt's mortality rate accompanying wounds of the colon alone was 11 per cent, our mortality rate for wounds of the large intestine alone was 18 per cent. These rates seem remarkable.

One interesting feature was that in 39 of our 70 patients more than one abdominal viscus was penetrated; this does not include the instances in which the same viscus might have sustained multiple perforations. The additional viscera involved were the liver, kidney, spleen, jejunum, ileum, stomach, urinary bladder, gall bladder, and pancreas. Frequently, these other structures had sustained damage sufficiently serious to have played the major if not the deciding part in the outcome for the patient. There were no cases of major intra-abdominal vascular damage in this group although extensive bleeding from the small vessels in the mesentery and wall of the gut was encountered. In the 2 instances (case 45 and case 28) in which the patients died after extensive shock had prevented surgical treatment, the intra-abdominal bleeding had been a major factor.

Shock. Jarvis, Byers and Platt said concerning abdominal wounds, "The seriousness of the shock picture is the most reliable prognostic sign.

TABLE III.—THE RELATIONSHIP OF SHOCK ON ADMISSION TO MORTALITY IN 125 CASES OF ABDOMINAL WOUNDS (JARVIS, BYERS, AND PLATT)

Shock, degree of	Cases	Mortality Per cent
None	37	10.3
Moderate (blood pressure less than 100 systolic, pulse more than 60 and objective signs)	33	31.4
Severe (blood pressure less than 70, (systolic) pulse more than 80, and objective signs)	13	60.6

TABLE IV.—RELATIONSHIP OF SHOCK ON ADMISSION OF PATIENT TO MORTALITY IN 957 CASES OF GASTROINTESTINAL PERFORATION¹

41 to 70		0.7	50.4
71 to 100	50	.6	18.0
to 20	46	10.4	8.1

¹Imes reproduced this table from the data submitted to the army by Torsy, (Systolic, in millimeters of mercury)
²Interval in hours between the time of wounding and the time of operation

In those cases not exhibiting clinical shock, mortality is less than 10 per cent, while in those in profound shock mortality is more than 60 per cent. They presented a table (Table III) based on 125 cases. Imes (19) also presented the relationship of shock to mortality (Table IV).

Tables III and IV show that the mortality rate in abdominal wounds bears a direct relationship to the degree of shock present on admission of the patient to the hospital. Shock which occurs during the operative procedure also seems of importance as a prognostic guide. Shock was recorded as being present during the operative procedure in 27 of our 68 cases in which operation was performed for large intestinal wounds. Sixteen of the 27 patients exhibiting shock during the operation died, a mortality rate of 59.2 per cent. Among 41 cases of operation for wounds of the large intestine in which shock was not recorded during the operation death occurred in only 1 case.

We think, therefore, that if shock is present before or during the operation as little surgical treatment as possible should be carried out, compatible with saving the patient's life. In such cases, extensive mobilization of the colon should be avoided and a faster less shocking procedure should be employed in the treatment of wounds of the colon if feasible.

TABLE V — THE RELATIONSHIP OF CONTAMINATION OF THE PERITONEUM TO MORTALITY (JARVIS BYERS AND PLATT)

Condition	Cases	Deaths	
		Number	Per cent
No peritoneal perforation of hollow viscera	13		
All intraperitoneal perforations	90	15	15
Perforations of stomach and small intestine only	43		20
Perforation of colon	57	26	46

Fecal contamination Jarvis, Byers and Platt wrote Contamination of the peritoneum by colon content is the single most lethal factor producing death in abdominal wounds. They present a table (Table V) to support this statement.

In our cases in which gross fecal contamination of the peritoneum by the contents of the large bowel was recorded, we noted that the mortality rate was more than twice as high as in cases in which no such contamination was recorded. *Extra peritoneal* wounds of the rectum are not included in this analysis (Table VI). It is interesting to observe that 64 per cent of the patients with this type of gross contamination had been in shock preoperatively. This emphasizes the role of peritoneal contamination in the production of shock. Of the 7 patients who were in a state of shock before operation, all died except 1.

Peritonitis as seen after rupture of an acute appendix, with the diffuse spread of seropurulent fluid, never was encountered. What were seen, instead, were general or local accumulations of blood most often mixed with intestinal contents, and associated with varying stages of peritoneal irritation. The peritoneum was reddened to a greater or lesser extent, in direct proportion to both the amount of contamination and the time that had elapsed since the injury. The men in cases 11 and 67 exhibited this picture to a marked degree and it is believed that it was an important factor in the profound shock sustained by these men.

TABLE VI — THE RELATIONSHIP OF GROSS CONTAMINATION OF THE PERITONEUM BY CONTENTS OF THE LARGE BOWEL TO MORTALITY

Condition	Cases	Deaths	
		Number	Per cent
Gross contamination		7	64
No gross contamination	42		8

Time interval, hours	Cases	Mortality Per cent
to 6	136	31.3
6 to	171	37.4
to 9	163	38.7
9 to	60	39.3
43		71

In our cases cellulitis and the formation of abscesses were rarely encountered at operation which is only natural, when one considers the time interval. One patient (case 12) was found to have early phlegmonous cellulitis of the entire ascending portion of the colon with involvement of the regional retroperitoneal tissue. In another man (case 37) a small retroperitoneal abscess adjoining a damaged descending colon had already developed. In both of these patients the interval between the time of wounding and that of operation was long.

The time lag The surgeons in World War I were unanimous in their emphasis on the need for early operation and speed during the procedure. They advised a short period of resuscitation with rest and the use of warmth and stimulants in most cases of shock. The surgeons of World War II for the most part placed much less emphasis on early operation and on speed during the procedure. Some of the ideas of and results obtained by surgeons with much experience in abdominal wounds in World War II follow.

Hurt wrote "A short time-interval is desirable, particularly in the presence of increasing peritoneal contamination and continuing hemorrhage. In our experience a short time-interval has not contributed materially toward a decreased mortality in intra abdominal injuries because some of the most severely wounded came to surgery who would have died had the time-interval been longer."

Jarvis, Byers, and Platt gave the figures seen in Table I for a series of 110 cases of abdominal wounds with intraperitoneal perforation of a hollow viscus.

Imes (17) thought that in abdominal injuries the extent of the wounds and the presence of shock are so much more important that they may eclipse the time lag itself. His impression was that infection which is so greatly influenced by time lag has been greatly diminished as a factor in mortality as a result of chemotherapy. He presented

TABLE VIII.—THE RELATIONSHIP OF TIME LAG TO MORTALITY IN 247 CASES OF ABDOMINAL WOUNDS (OGILVIE 28)

Lag, Hours	Cases	Mortality Per cent
0	15	25
6 to 1	76	1
to 12	41	90
12 to 24		48
Over 24	35	31
Not known	0	

a group of cases from an auxiliary surgical group reported by Chunn and Hauver (Table VII)

Ogilvie (28) said, An increased time lag works both ways, but chiefly toward a lower operative death rate. Delay brings peritonitis but it also eliminates the worst cases (Table VIII)

Bradford, Battle, and Pasachoff wrote 'Our experience has shown that the time interval before operation is not the most important factor in determining mortality rates unless there is evidence of continued internal bleeding or evisceration. We have had good results with some patients operated on over 36 hours after injury

In Morgan's series of wounds of the rectum the mortality rate was about the same whether there had been a long or a short interval between the time of wounding and the time of operation

Laufman, who reported 35 cases of penetrating wounds of the extraperitoneal portion of the rectum with 3 deaths, noted that there was an average time lag of 21 hours, with extremes of 8 and 55 hours. One patient, who had a perforation of 1 cm. was seen 6 days after he had been wounded he was treated without operation and had no complications during the 2 days his condition was followed up. One patient seen 38 hours after he had been wounded was operated on and was found to have spreading pelvic cellulitis, which was treated by drainage of the perirectal space. At the time he died he had in addition to this infection a clostridial gas-producing infection of the thigh

Our own experience is presented in Table IX. Only the 53 of our 70 cases in which the time interval was recorded are presented in this table

On the basis of the tables presented herein, it would seem that the time between wounding and surgical treatment was of almost no importance. But common sense tells us otherwise. There are many facts that we do not know. These tables deal with the men who underwent operation, which involves the selection of individual surgeons. Many surgeons operate first on those patients who con-

TABLE IX.—RELATIONSHIP OF TIME ELAPSING BETWEEN WOUNDING AND SURGICAL TREATMENT TO MORTALITY IN 53 OF 70 CASES OF WOUNDS OF THE LARGE INTESTINE PRESENT SERIES¹

Time Interval Hours	Cases	Deaths	
		Number	Per cent
Less than 6	0	0	0
6 to 12			45.4
12 to 24			
Over 24			50

¹Of the total series of 70 cases concerned in this article, these 53 are the cases in which the time interval was recorded. Of the time interval in the remaining 17 cases we have no knowledge.

stitute the worst risk. Only those patients who reached a hospital are represented in these tables. Among those who did not reach a hospital, what role did the time lag play? Obviously in a patient with a severed artery the time lag can be the difference between life and death.

We think the time lag is of great seriousness in certain cases in which the situation is desperate, as we shall indicate in the section of this article dealing with desperate conditions. However the time lag in the usual case does not seem to be of too much importance. Certainly many patients with serious wounds of the colon and rectum become well despite a time lag of many hours and even days. This change in attitude toward the time lag from that held in World War I is due in great part to new methods of shock therapy in the field. The modern system of supply of blood and plasma is of tremendous and obvious value to the patient a general condition. The sulfonamides and penicillin probably also were of considerable value.

The importance of the time lag should not be minimized however. In abdominal wounds, and especially in those involving the colon and rectum, severe contamination may be present, with the loss of blood into the damaged tissues. We think every effort should be made to shorten the time lag. We believe that the best results are secured by getting the patient in condition for operation as quickly as possible after injury

Evisceration Evisceration of the omentum or of the small or large bowel, was seen in cases 18, 32, 34, 35, 39, 40 and 52. There was 1 death in these 7 cases, a mortality rate of 14 per cent. The incidence of this complication in our 70 cases was 10 per cent.

Management of the patient in desperate condition Many agree that the time lag is most important for the more desperately injured patients who have

responded poorly to shock therapy. Some of these were not operated on, but were left to die. In many reported series of abdominal wounds the condition of the patients considered inoperable often is described as moribund. Some of these patients, if operated on might have been saved but if left alone they usually die. They constitute an interesting group and one which has stimulated considerable thought. In this respect, we shall present some of the ideas of surgeons who have had considerable experience with abdominal wounds in World War II.

Jarvis, Byers and Platt wrote

It has been generally agreed by surgeons of this war that with few rare exceptions, celiotomy and surgical repair are indicated in any wound involving the contents of the peritoneal cavity and also in wounds of the extraperitoneal rectum in order to divert the fecal stream. With this in mind we have operated upon every patient regardless of risk, believing that even though there be but the slightest chance of survival, we have been unable to take the responsibility for decision not to operate. The occasional survival of a patient who has suffered what has appeared to be a lethal wound has strengthened us in this attitude.

Regardless of time lag it has proved profitable to operate upon all patients with intraperitoneal perforation of a hollow viscus. After an adequate replacement of blood and plasma loss, in an hour to an hour and a half's time, if there is little or no response to shock therapy, there must be active causative factors responsible. In the main there are four such mechanisms, most of them amenable to surgery: (a) continued hemorrhage usually concealed; (b) severe fecal contamination of the peritoneum; (c) disturbance of the cardiorespiratory mechanism from thoracic injury; (d) early fulminating anaerobic infection with gas-forming organisms. Blast injury to viscera and massive evisceration less frequently prevent response. If there is no response to shock therapy or if response has begun but is interrupted and the patient's condition begins to deteriorate operation is begun without delay.

Bradford, Battle and Pasachoff wrote

"Our policy has been to restore these patients to the best possible condition prior to operation regardless of the length of time that has elapsed between the time of injury and the time of admission. Usually a patient with a blood pressure of below 80 systolic will not tolerate major surgery. However we have seen some patients who despite the usually adequate shock therapy do not respond by increased blood pressure. We feel that these patients, too, deserve the benefit of surgery, even

though the prognosis is not hopeful for their surviving the operative procedure. Of our 63 post operative deaths 17 occurred during the operative procedure. Had we not attempted operation these patients would surely have died but would have been considered nonoperative deaths. However we have had a number of similar cases who appeared as hopeless operative risks but did survive major operative procedure to go on to recovery. It is this group of patients that has made worth while the undertaking of surgery in the bad risk cases."

They presented the following example of a patient who constitutes a bad risk and for whom the final result was successful.

Case 1. A soldier wounded 9300, July 28, was admitted to the hospital 1,500, same date. He had a penetrating wound of the left chest due to bomb fragment. He was in profound shock, dyspnea was marked, and pulse was very severe. There was external bleeding from the wound, and physical examination suggested the presence of a left hemothorax. Roentgenologic examination disclosed the presence of fluid in the left chest and also bomb fragment in the abdominal cavity.

One thousand cubic centimeters of whole blood were given. The blood pressure failed to rise above systolic 64, diastolic 40. Because the patient showed evidence of continued bleeding he was prepared for immediate operation. Under intratracheal positive pressure anesthesia with nitrous oxide, oxygen and ether open thoracotomy was performed. The chest cavity as found to contain omentum and the transverse colon, the latter almost completely transected, fecal contents were free in the pleural space. A severely lacerated spleen, bleeding actively, as also present in the chest cavity. The left lower lobe of the lung as found to be lacerated.

The operative procedure consisted of suture of the laceration in the lung, splenectomy and repair of the multiple lacerations in the diaphragm. Closed system catheter drainage was provided. The abdominal cavity was then explored through midline incision and all blood was aspirated from the peritoneal cavity. The severed ends of the transverse colon are brought out through stab wound as colostomy. The abdomen as closed without drainage.

The patient, as given 1,000 c.c. of whole blood during the operation during which time his general condition remained unchanged. Postoperative therapy included an additional 500 c.c. of whole blood and continuous intranasal administration of oxygen. Wound suction drainage as instituted and continued for 3 days. The patient as given 40,000 units of penicillin every 4 hours and sulfadiazine 1 gram. Blood level of between 3 and 1 mgm. per 100 c.c. A total of 25 gm. of sulfadiazine and 80,000 units of penicillin as given.

The patient had mild postoperative course. The highest temperature postoperatively was 100.6° F. pulse 90. Drainage from the catheter in the pleural space was considerable. The catheter as removed on the third day. Hematocrit was present for the first few days but cleared. On the seventh day 800 c.c. of straw-colored fluid was aspirated from the left pleural cavity. The patient's progress had been considered satisfactory and he was therefore evacuated to rear hospital on the ninth postoperative day.

Beecher said

"In other cases an individual's wound may be such that definitive surgery is a necessary part of his resuscitation when profuse internal bleeding is occurring it is wasteful of time and of blood to attempt to get the patient's blood pressure up to normal. One should consider himself lucky if a systolic pressure of 80 to 85 mm Hg can be achieved and then surgery undertaken. This applies as well to other common conditions where full resuscitation is often impossible until the situation has been corrected surgically for example where wide fecal contamination of the peritoneum has occurred where leakage into and possibly absorption from, devitalized tissue is in progress.

We think that patients who do not respond to shock therapy after it has been employed briefly and vigorously for an hour or two and patients who do respond to such therapy but then begin to relapse have their only chance in operation and that they should be given this chance. The condition of our 2 patients (cases 45 and 28) who were not operated on was somewhat similar to the condition of the patient in the case quoted from Bradford Battle, and Pasachoff. The condition of our patient (case 67) who was operated on was a very similar type of desperate condition we lost this patient during the induction stage of anesthesia. Injury from blast or fulminating infection with anaerobic gas-forming organisms elsewhere in the body should be ruled out as a cause for shock before abdominal surgery is attempted.

OPERATIVE TREATMENT OF WOUNDS OF THE COLON IN GENERAL, AND OF COMPLICATIONS

The operative treatment of wounds of the large bowel still is a field of controversy. There are those who think that all wounds of the colon that can be exteriorized should be exteriorized. Others still believe that suture alone has a place of importance. A consideration of the different methods and pertinent facts concerning them needs reviewing. This we have done, and we shall present our results in this section. Because wounds of the colon and wounds of the rectum present different problems they will be considered separately.

General considerations Before beginning the operative procedure on a wound of the colon the surgeon must bear in mind the fact that this type of wound in general is severe and that the morbidity and mortality rates are high. The general condition of the patient must be carefully considered and observed. Shock was the cause of death in the majority of our cases in which the out-

come was fatal. Thus, as a rule the less shocking the procedure employed, the better.

The procedure chosen should prevent sepsis, which so often is the result of the wound in the colon. It should also prevent debilitation. When ileostomy is performed debilitation is threatened because of the loss of nutrition which the ileac stoma entails especially in respect to fluids.

In the operative treatment of wounds of the colon the following five methods are commonly employed individually or in conjunction with each other.

First, the wound in the colon may be sutured. When this is the only method used it is called 'simple suture, primary suture suture alone or suture with replacement. All these terms mean that the sutured wounded segment of colon is left inside of the abdominal cavity.

Second, deviation of the fecal stream from the wounded segment of colon may be accomplished. This procedure usually is carried out in the form of a colostomy performed proximal to the wounded part of the colon. It is often combined with suture of the wounded portion of the colon and is then spoken of as suture with proximal colostomy. Ileostomy or ileocolostomy can be performed.

Third, exteriorization may be used. This may imply anything from the bringing out of a small tear at the apex in a loop colostomy to resection of a damaged segment of bowel and the bringing out of the ends as in the performance of double-barreled colostomy.

Fourth resection may be done. This term applies to resection of the wounded portion of colon regardless of what is done with the remaining part, such as exteriorization suture, or anastomosis.

Fifth drainage from a retroperitoneal wound to the exterior may be established. This is done occasionally through the flank for retroperitoneal wound, of the ascending and descending portions of the colon, and is often used for extraperitoneal wounds of the rectum.

Historically these basic methods are not new. In World War I all were used. The following is quoted from *The Medical Department of the United States Army in the World War* (26).

"The general principles to be followed are. Suture whenever possible to secure a satisfactory closure, and always employ a double row of sutures. Avoid resection colostomy is to be preferred. Colostomy is to be advised with large ragged openings, particularly those occurring in the cecum, descending colon and sigmoid. The wounds that are sutured do better than those in which an artificial anus is employed the latter group gives the high mortality of 70 per cent.

TABLE V.—RESULTS OF SURGICAL TREATMENT OF WOUNDS OF THE COLON IN WORLD WAR I COMPARISON WITH OGILVIE'S SERIES IN WORLD WAR II

Series	Mortality rate Per cent
Wallace, 947 (37) (Operated patients)	28.7
Fraser and Drummond, 97 (83 cases of surgery of colon)	25
United States Army (26) (No statement as to surgery)	30.4
Drummond, 91 (37 cases of surgery of colon)	45
Ogilvie, 211 (128)	2

In the British Army Fraser and Drummond who had a large experience with wounds of the colon in World War I discussed the question of treatment thus:

"The actual operative treatment may be summed up in the following methods: (1) Simple suture, (2) Suture with a proximal colostomy, (3) Colostomy at site of injury. The operation of resection may be left out of account. It is rarely advisable to practice it in this type of surgery.

"At first we followed the practice of a proximal colostomy in combination with the operation of suture. There are the obvious advantages that it increases the safety of the suture while it obviates the passage of fecal matter through the damaged gut. At this time we were suspicious regarding the viability of the line of colon suture and we felt that the colostomy added greater security. Later we recognized that the performance of proximal colostomy was rarely necessary and we have therefore almost abandoned its use. We now reinforce the suture line by an omental graft. We believe that our results have improved since we have altered our procedure. When the wound of the colon is very extensive colostomy at the site of injury is the only possible procedure.

Thus, the opinion of the surgeons at the end of World War I was that suture was the method of choice except in large wounds, for which colostomy performed at the site of injury was the treatment of choice.

During the interval between the two world wars little advance was made in the operative treatment of wounds of the colon and rectum. Generally suture of the wound was employed when possible, and exteriorization was reserved for large wounds of the colon. The mortality rate among civilian patients remained high. The mortality rate in wounds of the large bowel reported by Rippey was

62.5 per cent by Wilkinson and associates, 62.5 per cent when only the large intestine was wounded and 79.3 per cent when there were wounds of other viscera also and as reported by Elkin and Ward, 53 per cent. These percentages constitute a good cross section of the mortality rates in cases of injuries in civilian life in this country. In abdominal wounds among civilians the patient often is brought to a hospital and operated on early whereas in the surgery of war the delay is much longer which largely eliminates the patients who have sustained injuries to large vessels, such as would be seen in civilian hospitals. In other respects, also, there are differences. It is noteworthy however that in none of the civilian series were the amounts of blood and plasma administered as large as those employed in the army series in World War II.

With World War II came the wide application of exteriorization with disease of the suture method. Now that the war is over it may be of value to consider the results from World War II as contrasted with those from World War I, and to try to evaluate the place of the main operative procedures at our disposal.

Today in war surgery among the Americans and British the general practice is not to employ suture of wounds of the colon, but, instead, to use exteriorization of the wounded segment of colon. Great emphasis has been laid on this method by the British and American army surgeons. Cutler, in reviewing the military surgery of the United States Army in the European Theater of Operations, remarked "All large bowel injuries should be exteriorized by the simplest method available.

Injuries below the rectosigmoid, which cannot be exteriorized must be closed and a complete diversion of the fecal stream carried out proximally to the sutured area."

This, then, was the policy of our army in Europe. Exteriorization was widely used by the British army in Africa and in Europe.

Exteriorization. Some attempt may now be made to evaluate the procedure of exteriorization which has gained such wide favor in the treatment of wounds of the colon. To do so other operative procedures must, of necessity, be considered, especially suture with replacement and suture with replacement combined with proximal colostomy.

Ogilvie (28) in World War II came out strongly in favor of exteriorization in almost all wounds of the colon. His policy was employed in the British Eighth Army in the western desert of Africa and the results were encouraging. There were 86 deaths in the 160 cases of wounds of the colon treated surgically and reported by him, a mortality

rate of 53 per cent. It is seen when this rate is compared with figures from World War I that it represents a definite improvement (Table 10).

When the colon was the only abdominal organ injured, Ogilvie (28) listed 37 cases associated with a mortality rate of 40 per cent. Wallace in 1917 reported a mortality rate of 58.7 per cent in cases in which no other lesion of the alimentary tube was present. Wallace's figure was based on 965 cases of abdominal injuries treated surgically in which the colon was wounded 252 times. As compared with the World War I figures Ogilvie's results are much better than the figures would indicate as is shown by Ogilvie's analysis.

In comparing this series with any in the last war it must be pointed out that the conditions of operating in the Western Desert were at most times far worse than in a C.C.S. in France and that many more severe cases were tackled than ever reached the operating theater in 1918. Then many men died at Field Ambulances, and of those reaching a C.C.S. 20 per cent were regarded as moribund and unfit for operation. Even in the comparatively mild group of injuries limited to the alimentary canal, it is noteworthy that in the Middle East series 45.4 per cent of the wounds involved structures other than the small intestine in the last war series only 32 per cent. Every man that could be resuscitated was resuscitated, and every man that could be brought to the table alive was tackled unless there was another with a better chance in urgent need of surgery at the same time. It is probably true to say that two-thirds of the men who died in the first 24 hours (i.e. 42) would have been excluded from 1918 statistics.

A further point of difference is that 98 per cent of these patients were traced to the base, whereas in the figures of the last war most of the statistics dealt with survivals in the forward units only. On such a reckoning 25 of the deaths in this series would have been recorded as survivals.

In 1946 Ogilvie (29) had this to say regarding wounds of the colon:

"I felt at the beginning of the war (World War II) that the increased safety brought to civil surgery of the colon by the principles of exteriorization and proximal exclusion pointed the way to improved results in war surgery. I made a big point of this in a lecture in 1940 from which I quote the following:

There has been a marked tendency in recent years to look on the large intestine with increasing respect or even fear. Its walls are thin its blood supply is poor and the peritoneal coat is interrupted by a broad mesentery and distorted by fat

blisters, the contents are highly infective and mechanically traumatic its luminal pressure alters with explosive suddenness. No sutures can be placed accurately in its wall and what are thought to be lemmerts often pass through all coats and carry infection. All surgeons have experienced trouble with leakage and sepsis at the suture line after resection and many feel today that no stitch should ever be put through a colon that is not both empty and sterile. A colostomy or a resected loop should not be stitched to the skin but the skin opening should be made to fit the colostomy, a segment of bowel should not be excised and the ends sutured unless the contents have been diverted above by an excluding colostomy for at least two weeks. Devine has shown the way to success in cancer of the colon by his operation of exclusion and Lahey has made resection of the rectum for cancer and of the colon for ulcerative colitis safe by stage operations in which the bowel is brought to the surface. In war injuries the way to safety is the same for caecostomy provides only partial relief of tension at the injured site, and proximal colostomy is no better unless it is done some weeks before.

My early experience in the African Campaigns confirmed this view: that is, I saw far more avoidable deaths due to unwise suture of colon wounds than I saw suffering from colostomies or difficulties in closing. The young surgeon fails to appreciate that a small hole in the colon caused by a projectile is really a small hole surrounded by a much larger area of devitalisation that will eventually slough. When he has learnt the limits of good and evil, that is the point when tissues cease to be viable even though they look good, he can begin to use his judgment. In practice, to an experienced abdominal surgeon the nearer a wound is to the ileo-caecal sphincter the more often it can be sutured, the nearer to the rectum the more often it must be exteriorised. But when suturing large intestine wounds I feel that drainage down to the lesion is always wise and a proximal decompressing or defunctioning opening usually so.

He continued and discussed the place of suture alone, suture with proximal colostomy and exteriorization. Then he discussed the treatment of the right and left portions of the colon.

1 Suture alone should, I think, be reserved for small holes in the caecum or the mobile part of the ascending colon. The surgeon must be sure that his infolded suture line is through completely healthy bowel wall, and he will be well advised to lead a small drain down to it.

2 Suture with proximal colostomy is clearly right for wounds of the rectum that can be sutured

TABLE XL.—WAR WOUNDS OF THE LARGE INTESTINE: METHODS OF OPERATIVE TREATMENT AND MORTALITY RATES THEREOF: VARIOUS REPORTED SERIES

Author	Primary suture			Suture proximal colostomy or caecostomy			Exteriotisation without resection			Resection with ileo-transverse colostomy			Resection with extirpation			Resection with anastomosis (colocolostomy)			No operation

without mobilisation for no other policy is possible. Suture with proximal caecostomy is permissible to an experienced surgeon in local unlacerated wounds of the right half of the colon.

"3. Exteriotisation is the best method for dealing with the great majority of wounds in the left half and with lacerated or extensive wounds in other parts of the colon that can be extirpated.

"4. Injuries of the ascending and descending colon are, of course, among the most difficult problems encountered in the abdominal surgery of warfare, particularly injuries in the upper half where the bowel is more fixed and much deeper, where the abdominal wall is fixed by the ribs, and where an injury to the kidney is a common complication. Wounds of these parts, unrecognised or untreated at the time often drain to the surface in the loin, and after leaking faeces for a week or two heal spontaneously but I feel doubtful whether intentional drainage to the surface that is, a lumbar colostomy without mobilisation is permissible. The surgeon in examining and dealing with a wound of this part of the colon necessarily opens up retroperitoneal planes in which anaerobic cellulitis is common and fatal, and if he is making a colostomy it should be well to the surface and not through this deep and dangerous area.

"I can only say that with injuries in the neighbourhood of the hepatic and splenic flexures, the surgeon must do the best he can within the general principles that lacerated tissues must be resected and faeces must not be allowed to leak into the abdomen. If the colon injury is a large one, he

must resect the damaged segment, and somehow bring the ends together. On the left side a double barrelled colostomy will be his aim, on the right he may accept the expedient of resection and suture with less musing. In each of these corners, however the problem may arise that, after the minimum adequate resection one or both ends will not come to the surface without dangerous tension, or without further extensive mobilisation that will take time the patient cannot stand, and open up fresh planes to a dangerous extent. To extirpate both ends at different parts of the abdomen is safe and simple. It leaves a most difficult problem of reconstruction for the surgeon who follows. In such cases end to end suture with proximal colostomy or caecostomy may be the best way out. For extensive injuries on the right side, a classical right colon resection with end to end ileo-transverse anastomosis may easily be the simplest and most rapid and therefore the correct procedure. Anastomosis between small and large intestine has few of the risks of colon to colon anastomosis, since the material passing the suture line is fluid not very infective, and flowing at an even rate and low pressure. In big lacerations around the splenic flexure, which often imply repair of the diaphragm, suture of the fundus of the stomach and removal of the left kidney, double barrelled colostomy may be quite impossible, and end to end suture with wide local drainage and proximal caecostomy or right transverse colostomy will be the most satisfactory method of dealing with a pretty nasty situation.

TABLE VII.—MORTALITY RATES IN THE SURGICAL TREATMENT OF WOUNDS OF THE COLON WHEN ONLY THE COLON WAS INJURED

Series	Procedures employed									
	Suture alone		Suture and proximal colostomy		Exteriorization				Resection and anastomosis, colon-to-colon	
	No.	Died, Per cent	No.	Died, Per cent	No.	Died, Per cent	No.	Died, Per cent	No.	Died, Per cent
Porritt	3	33.3			95	21.4				
Ogilvie (18)†	4		1	11	N resection		Resection			
					40		100		100	

†Patients who did not die of wounds other than wounds of the colon.
 ‡Patients operated on within 48 hours of time of wounding.

Thus, Ogilvie thought that all three of the methods being considered in this section of the present article as well as resection have a place in war surgery.

Gordon Taylor likewise believed that all three methods and resection have an important place. He stressed exteriorization, and wrote that he thought it should be done whenever possible. He declared that suture with replacement is certainly safe in early tears and lacerations if these lesions are intraperitoneal, but advised that a graft of omentum or an epiploic appendix be used to reinforce the suture line.

Suture. Suture alone, with replacement of the sutured colon in wounds of the colon was frowned upon during World War II by the American and British alike. The attitude was that this procedure was unjustifiable the result may be successful, but an unnecessary risk will have been taken (1). We shall now present some opinions and facts concerning this still controversial method of treatment. As is shown in tables 11 and 12 this method was accompanied by a lower mortality rate than that associated with any other method. When suture was employed the mortality rate was 22 per cent, in contrast to a rate of 39.1 per cent when exteriorization without resection was carried out.

To judge this procedure, the fate of the suture line should be determined that is whether or not leakage occurs. Jolly writing about his experiences in the Spanish Civil War said:

"It is only in the treatment of small tangential wounds, or of small perforations of the mobile portions of the colon, that good results may be anticipated from the simple invaginating suture practised so successfully in the treatment of wounds of the small intestine.

"The larger tears and retroperitoneal wounds of the fixed portions of the colon are so often com-

plicated by extensive haemorrhagic extravasations into the intestinal coats or into the mesocolon that suture is both difficult and usually even if carried out carefully by layers, unsuccessful. There is too great a danger of the whole damaged wall of the gut sloughing away on the fifth or sixth day after operation.

Jolly did not mention the use of exteriorization. Almost no cases were recorded in World War II in which the sutured wound in the colon broke down. Imes (17-19) treated 25 patients with war wounds of the colon by suture alone, and in no instance were there complications arising from leakage the wounds apparently all remained closed. He collected 168 cases in which suture alone or suture combined with proximal colostomy had been the method of treatment. He wrote:

From our experience and from what I was able to gather I had a definite belief that many of the perforations would have fared better if they had been treated by that method. As to the size of the perforations which might best be sutured, I would say one under four centimeters in diameter although that is purely an arbitrary figure. I think the location of the perforation in relation to the mesentery is important, since for obvious technical reasons those involving the mesenteric portion of the bowel circumference are more difficult to close satisfactorily.

He thought that extensive mobilization at times necessary for exteriorization, is a most important factor in the production of shock.

Suture alone was used by us twice without any leakage from the suture line (cases 1 and 19). In both instances the wound was small.

Giblin cited 4 deaths in cases in which the injured part of the colon was sutured without performance of proximal colostomy but he did not disclose whether or not leakage from the suture

and Ogilvie (28) Serious septic complications can occur also when the exteriorization method is employed.

As reported by Gordon Taylor and by Roettig and his associates an exteriorized loop of bowel after colostomy can retract down below the level of the abdominal wall and into the interior of the abdomen with disastrous results. We have seen an exteriorized loop of bowel become necrotic and retract into the abdomen. Also fecal material can drain down between the colonic stoma and the wall of the bowel into the abdominal cavity and form an intraperitoneal abscess as probably happened in one of our cases (case 29) Retrocolic abscess occurs.

Jarvis and associates wrote

"The retroperitoneal tissues exposed to extensive contamination by the mobilization of attached colon have been a frequent source of infection. In fact the most frequent situation for the development of abscess next to the subphrenic areas.

Infection sometimes severe, in the laparotomy incision occurs if the wounded portion of colon is exteriorized through this incision. This infection can be serious, and dehiscence can occur because of weakening of the wound by infection.

Acute and complete intestinal obstruction and also incomplete obstruction were reported by Roettig and associates as late complications of exteriorization. Obstruction was not an uncommon complication. In some cases, the small bowel had become adherent at the site of exteriorization. Early, we noted abdominal distention by the accumulation of gas in the colon proximal to an opened exteriorized loop of bowel. This is relieved simply by cutting across the loop which should be done, as a rule, before a patient is evacuated to the rear.

In the cecum and ascending portion of the colon the performance of colostomy can result, in some cases, in severe and dangerous loss of fluids and valuable nutrition. This material can be of liquid character and it can be most irritating to the skin and damaging to any incisions it encounters.

Shock occurring during the operative procedure of mobilization of a large segment of bowel in order to exteriorize it often complicates exteriorization. This complication has not been emphasized in the literature. We had 24 patients for whom mobilization of some part of the colon was done. Fifteen of these patients went into shock during the operation. Four patients were not in shock during the operation. In 5 cases the condition of the patient was not stated. Ten of the 24 patients died and all 10 were in shock during the operation. On reviewing these cases we believe that the patients

did not seem to be any more severely wounded than others who had sustained wounds of the colon. In some of these mobilization operations other procedures of less shocking nature could have been used. We have noted that mobilization often causes a marked decrease in the blood pressure often is time consuming especially in inexperienced hands, and sometimes is accompanied by soiling of the peritoneum by fecal matter.

Advantages and disadvantages of exteriorization versus suture. The advantage of exteriorization lies in the fact that the danger of continued fecal contamination of the abdominal cavity is almost eliminated and that decompression of the large bowel can be effected if the exteriorized portion of bowel is opened. Thus in war injuries, the surgeon feels sure that after exteriorization the source of contamination is safely outside of the abdominal cavity and that distention of the large bowel can be controlled. Patients so treated therefore can be evacuated to the rear under less surgical supervision than those treated by suture alone. The disadvantages of exteriorization are several. The extensive mobilization necessary for exteriorization may so endanger the patient's general condition by the production of shock as to be fatal. Secondary operations are necessary to close the colonic stoma and the nursing problem is made worse by the need for frequent change of dressings.

The advantages of simple suture are its simplicity, speed, nonshocking aspect, elimination of the nursing problem, avoidance of later operations, and shorter convalescence of the patient. The disadvantage is that the suture line might break down with contamination of the abdominal cavity. More surgical supervision therefore is needed at first to insure watchfulness for this complication. Suture with proximal colostomy increases the safety of the suture line and often can be used in place of an extensive shocking mobilization procedure.

Summary exteriorization suture with proximal colostomy and suture alone. In summary we evaluate these three methods of treatment in war injuries of the colon as follows. Exteriorization is an excellent procedure, and is our method of choice in most situations if mobilization is not necessary. If mobilization is necessary to exteriorize the wound and if the patient's general condition is poor then the less shocking procedure of suture with proximal colostomy is better. In severe wounds exteriorization is the only choice as a rule, for such wounds cannot be sutured without considerable danger of breakdown of the suture line. In small wounds—those less than 2 or 3 cm in diameter—suture with proximal colostomy is very

safe Suture alone in small wounds probably is a sound procedure. The sutures must be placed in viable gut only. Two layers should be used, and the suture line should be reinforced, if possible, by a graft of omentum or by an epiploic appendix. A drain should be inserted down to the suture line. We think that in war wounds the sutured segment of colon should be safeguarded by some form of proximal deviation of the fecal stream or by exteriorization of the sutured segment. Occasionally in war wounds of the colon suture alone is advisable in selected cases in which damage to the gut is minimal.

Resection Resection of a wounded segment of the colon has not been employed often, and no large series concerning such treatment has been reported. Probably no one surgeon has seen resection of the colon done many times for the type of injuries under consideration. Among those men who have had experience with resection under such circumstances there is almost uniform agreement that the procedure is best avoided if possible because it is too severe a shock to the patient. In World War I resection of the colon was considered to be too shocking. In the Spanish Civil War Jolly employed resection of the colon in large wounds of the colon because he found that suture of such lesions resulted in sloughing of the bowel and death. Concerning these large wounds he wrote "It is in these cases, therefore, that resection of the colon, notwithstanding the appalling mortality rate, must be undertaken." He did not use exteriorization.

In World War II resection for wounds of the colon was used to a limited extent. Ogilvie (23) reported 22 cases, with a mortality rate of 64 per cent, in which resection with exteriorization was performed. He also reported 2 cases, in both of which death ensued, of resection of the colon with anastomosis. His views concerning resection have already been presented in this article in the section on exteriorization. He thought resection sometimes is the best treatment for large wounds of the ascending and descending portions of the colon, especially in the ascending portion. Hurt reported 4 cases of resection of the terminal portion of the ileum, the cecum, and the ascending part of the colon, with the performance of double-barrelled ileotransverse colostomy with 1 death. Resection with exteriorization was performed once in the left side of the colon and the patient lived. These procedures were performed only in the presence of extensive injuries in a fixed portion of the colon. Gordon Taylor reported that General Fruchaud successfully performed resection of the right side of the colon 4 times consecutively for severe in-

jury direct anastomosis between the ileum and the transverse part of the colon being done. He cited another successful resection of the hepatic flexure with end-to-end junction. Gordon-Taylor thought that resection is the method of choice in certain conditions, such as when (1) the cecum or colon is in a state of infarction (2) there is extensive separation of the bowel from the mesocolon, especially if the latter is the site of a hematoma or is bleeding actively; (3) the vitality of the bowel has been crushed out of existence and (4) the gangrenous ulceration of Hamilton Drummond and Shaw Dunn is present. Thus, he advocated resection when the vitality of the bowel over an extensive area is gone or seriously threatened.

Jarvis and associates wrote "In those long, linear tears, especially in the proximal half of the ascending colon the most satisfactory answer seems to be resection of the proximal portion to beyond the tear ileotransverse colostomy (which we prefer to do in end-to-side fashion) bringing the proximal hepatic flexure or transverse colon out through a stab wound. They did not present cases.

All our own experience with resection was gained with wounds of the right portion of the colon, and it made us extremely wary of resection because of our high mortality rate. Before this series, while we were in North Africa, we carried out, once, resection of the terminal part of the ileum, cecum, and the ascending portion of the colon with double-barrelled ileotransverse colostomy and the patient withstood the operation well. In this series, right colectomy was performed 4 times (cases 5, 9, 11, and 12) at the primary operation. Only one of the patients had wounds other than in the right part of the colon. Two of these soldiers (cases 5 and 9) had arrived at our hospital in good general condition; these 2 survived the resection. The other 2 (cases 11 and 12) had come to us in severe shock. They were prepared by shock therapy preoperatively but during the operation went back into severe shock from which they never recovered. It is our belief that in both of these cases the performance of simpler shorter procedures might have been wiser.

After this, we encountered a patient with a severe tear of the cecum and ascending part of the colon (case 6). We exteriorized the injured part of the right portion of the colon and performed ileotransverse colostomy at the primary operation. Six days later we resected the exteriorized portion of the right part of the colon without anesthesia, and the patient did well.

Our attitude is that resection is a severe procedure to inflict on a patient severely wounded in

the abdomen. If some simpler procedure can be done we think it a wise policy to do it. The general condition of the patient should be considered seriously before any extensive resection of the colon is undertaken.

Drainage from a retroperitoneal segment of colon to the exterior Almost nothing has been written about drainage of a wound in the colon through the abdominal wall, as in the flank. In extraperitoneal wounds of the rectum institution of drainage from the outside down to the wound is an important and established method of treatment. In wounds of the retroperitoneal part of the colon such drainage apparently has been used but rarely and almost no reports of cases, analyses, or valuable experience with this method have been recorded in the published series of abdominal wounds.

Berry who was surgical consultant of the American Seventh Army wrote as follows concerning retroperitoneal wounds of the colon. "These wounds are debrided, a direct tract to the wound in the colon established first, then the abdomen opened well explored, and a proximal colostomy performed. He did not mention the results obtained in this method.

Larson (23-24) reported that he used a modification of this method in several cases, with success. He inserted a mushroom type of catheter into the wounds in the retroperitoneal part of the colon, and anchored it in place with a suture. He then brought the catheter and the long ends of the suture out through a stab wound. Traction was exerted to hold the wound in the colon against the stab wound. In one case he removed the catheter after 10 days the wound was healed 10 days later. His patients were operated on immediately after injury. His opinion was that retroperitoneal drainage now can be done with safety in retroperitoneal wounds.

As I have shown Ogilvie (29) in 1946 writing about wounds of the right and left portions of the colon said that he doubted if intentional drainage to the surface—that is, lumbar colostomy without mobilization—is permissible.

We used this method in only one case (case 1) in this series. The patient had two small perforations of the retroperitoneal part of the cecum which were sutured. The injured part of the cecum was not exteriorized but retroperitoneal drainage was established. No complication occurred. In Italy a patient came to us with a wound of the retroperitoneal part of the ascending colon. This had been treated by wide retroperitoneal drainage. He almost died of sepsis and loss of fluid such as occurs after creation of an ileac

stoma. Weeks later ileotransverse colostomy and right colostomy were performed. The end result was good. One patient (case 37) perhaps should have had this type of treatment for wounds of the retroperitoneal sections of both the right and left portions of the colon. Instead these wounded segments were exteriorized. The patient died of shock from this very extensive procedure.

Sound evaluation of this procedure cannot be made on the basis of the available evidence. We feel that perforating wounds of the retroperitoneal portion of the colon should be exteriorized if the patient's general condition is such that he will withstand the procedure. If suture of the wounded segment of colon is employed, without exteriorization proximal deviation of the fecal stream seems definitely advisable. This ought to be accompanied by the institution of drainage from the wounded segment to the exterior.

Colostomy An understanding of the colonic stoma from its establishment to its closure is necessary for anyone treating wounds of the large intestine. The colonic stomas resulting from the wounds of World War II were closed with little morbidity and practically without mortality. This being true the surgeon doing the early treatment of wounds of the colon and rectum can establish a colonic stoma with the knowledge that it can be closed later almost without risk.

Both the loop and the spur type of colonic stoma can be closed successfully by either the intraperitoneal or the extraperitoneal method. Thus, at early surgical treatment either the loop or the spur type of stoma can be employed, as the surgeon desires.

A brief glance at the type of work that was done on closure of colonic stomas of World War II is interesting. Roettig and associates operated on 92 patients with colonic stomas or fistulas and only 3 fistulas developed after closure. There were no deaths. Their patients were considered to have no infectious, and intraperitoneal end-to-end anastomosis was the routine treatment. Chemotherapy was an important part of the care. Pilcher and Nadeau closed 14 loop colonic stomas extraperitoneally with the development of 1 fistula. They had no deaths. Keene closed 50 colonic stomas or fistulas. Hamilton and Cattinach closed 43. Gregg and Mosely closed 23. Colcock closed approximately 23. In all of the series in this paragraph 243 colonic stomas or fistulas were closed without a death.

In the closing of colonic stomas in the war wounded the surgeon who does the definitive surgical work often is not the one who did the initial operation. Thus he does not know the exact an

atomic situation such as the length of the spur. The surgical notes often are brief. Intrapertitoneal closure with direct visualization of the loops of bowel allows the surgeon a better understanding of the situation. Short spurs, twisted loops of bowel, important arteries close to the colonic stoma, and the attachment of small bowel to the site of the stoma have been found at surgical exploration. These could have caused complications if a clamp had been applied blindly to the spur created at colostomy. In intraperitoneal closure the danger of peritonitis is increased. In a few instances among the cases of Roettig and his associates, in which signs of localized peritonitis developed, streptomycin was used and the signs disappeared.

The technique of performance of the spur type of double-barrelled colostomy varies somewhat in different hands. The main principle is to have a

sufficiently long spur to favor spontaneous closure, even though a secondary procedure to accomplish this end may prove necessary. A generous amount of each limb of bowel should protrude beyond the abdominal wall in order to discourage retraction.

Both the loop type and the double-barrelled type of colostomy should be performed through stab wounds, separate from the exploratory incision.

The technique of loop colostomy needs little comment other than that there should be absolutely no tension on the loop. It is most simply accomplished by the passing of a thick rubber tube or a glass rod through the mesocolon adjoining the bowel, and suspending it on the abdominal wall. The peritoneum should fit snugly but not too tightly about the emerging portion of the colon. There is rarely any need to suture the peritoneum to the colon.

Contribution to the Study of Salivary Neoplasms
(Contribuição para o estudo dos neoplasmas salivares) P. DEBAIVE and J. DICKERTS. *Arg. pat.* 1943 14 396.

This study is based on 53 cases of salivary neoplasms mostly parotid but including also submaxillary sublingual upper labial palatal and cervical neoplasms observed at the Anticancerous Center of Liège University from October 1925 to October 1941. Besides a complex pathologic anatomy these tumors present a special clinical aspect which makes surgical and radiologic treatment difficult. Histologically the authors distinguish simple epithelial tumors and remanipulated or mixed tumors which may be of localized and invading types. The remanipulated tumors differ from the simple tumors only in the respective relations of their epithelial and connective tissue elements. With the exception of rare adenomas and fibromas all epithelial tumors of the salivary glands are malignant in various degrees independently of their apparent structure. Like the other malignant tumors they possess the property of spreading locally by direct infiltration of the tissue of the involved organ regionally through the lymphatics and distantly through the lymphatic and blood vessels. In the authors' cases death occurred from local and regional invasion metastasis being rare. The growth of these tumors is sometimes slow and progressive sometimes rapid after a slow and progressive development sometimes rapid after an interruption and sometimes rapid from the beginning soon leading to death. Recurrences are very frequent following operation or irradiation there were 18 (32.9 per cent) recurring tumors 13 presenting one recurrence and the remainder developing from two to five recurrences.

The diagnosis must be based on clinical roentgen and histologic examinations. The differential diagnosis must be based on the same elements and, in addition on exploratory puncture which will allow distinguishing the tumors from certain lesions such as caseous bacillary adenopathies biopsy will be the last resort.

The prognosis depends on the histologic nature of the tumor its extent, early intervention treatment used, and the possibility of recurrence. The age at which the tumor appears has a notable influence before the age of 40 and beyond that of 70 the prognosis is more favorable than for the ages in between as the number of deaths increases gradually up to the age of 60 years. Localized mixed tumors as such do not cause death but recur frequently invading

mixed and simple tumors offer about equal probabilities of death.

Treatment must be conducted with the constant idea of avoiding local recurrence. The slowness with which the tumors usually evolve and the relative rarity of distant spread are reasons for deferring early intervention and other considerations which generally play an important part in cancerology. Efforts must be directed toward local destruction of the tumor for instance by curettage simple enucleation wide excision total removal of the gland removal of local and regional lymph nodes and irradiation (roentgen and radium therapy) combined or not with surgical intervention. Each method presents advantages and disadvantages and the indications will depend on circumstances. The disadvantages are scars salivary fistula and facial paralysis. Of the 53 patients 28 (52.8 per cent) were without tumoral symptoms after periods of from 4 months to 16 years. It seems that results could be improved by more rational use of the resources of radiosurgery.

RICHARD KESSL, M.D.

Diseases of the Salivary Glands. A. C. FURSTENBERG
J. Am. M. Ass. 1943 136 1

The etiologic factors responsible for inflammations of the salivary glands are foreign bodies—particularly by the calculi—injury or disease of the abdomen or pelvis and extension of infection from neighboring tissues. Injury and dehydration are also potent influences in the origin and development of infections in these structures.

Effective agents in the therapeutic armamentarium are sulfadiazine and penicillin. Hydration must be instituted and maintained. Wide incision and massive drainage are required when a circumscribed collection of pus is present.

Chronic infective granulomas are rare manifestations of disease of the salivary glands. A noncaseating form of tuberculosis is occasionally observed. The gumma perhaps is more rarely seen. Actinomycosis has responded most satisfactorily in many instances to the sulfonamide drugs and penicillin therapy.

A dysfunction of the salivary glands is occasionally the result of end organ lesions of the peripheral secretory nerves. A normal salivary flow may be produced by the administration of pilocarpine. The effect of the drug is augmented by the simultaneous ingestion of the acid forming salt ammonium chloride.

The common neoplasm of the salivary glands is the mixed tumor. The soft tumors are more prone to exhibit carcinomatous alterations than the hard, firm ones. They are devastating in their clinical behavior in that they tend to degenerate into rapidly

proliferating carcinoma. Surgical intervention which accomplishes the complete removal of the lesion is most successful. When these tumors do recur how ever they usually present frank carcinomatous alterations and further surgical efforts are futile.

EYE

A Cross-Sectional View of Injuries in an Ophthalmic Practice in Eire. EUTHAN MAXWELL. *Brit J Ophth.* 1948 32 134.

The author presents a cross sectional view of injuries observed in the practice of ophthalmology in Eire extending over three-quarters of a century. The cases are discussed from the viewpoint of (1) causation (2) types of injury (3) treatment and (4) medicolegal aspects.

Causation. A series of 796 cases are arranged in groups according to the age of the patients. Birth injuries occurred in 4 cases. Up to the age of 6 years, injuries resulting from sharp objects such as scissors, from falls, and from missiles such as sticks, stones and broken glass, occurred in 9 per cent of the patients. The group from 7 to 16 years of age which constituted 21 per cent of the patients suffered injuries resulting from organized and unorganized games, the national game *Hurling*, was responsible for the largest proportion of casualties of this type. It is recommended that air guns be licensed and that leaving dangerous materials such as quicklime and quicksand unguarded in the public streets or in builders' yards be considered a criminal offense. The group from 17 to 45 years of age constituted 46 per cent of the patients. Because the main industry is agriculture, metal splinters from farm implements, broken wire, nails, flying particles of stone in quarrying, road-making and repairing, thorns and branches accounted for the majority of injuries in this group. The use of protective devices for the eyes is advocated. In the group of patients from 46 to 65 years of age (20 per cent) the causes of injury were similar to those in the last age group. Wearing of the "middle distance" correction while at work helps to reduce the incidence of injury. In the group of patients who were over 65 years of age, injury occurred mainly while gathering and chopping sticks and during stresses and strains. Prevention is an individual matter.

Types of injury. The following arrangement shows the order of frequency of injury: (a) penetrating wounds of the eyeball, without entry of foreign bodies (36 per cent). The majority of injuries were corneal or corneoscleral and involved the lower segment; the uvea was affected in 55 per cent and associated cataract occurred in 50.5 per cent of the cases. (b) Contusions of the eyeball (22.5 per cent) resulted in damage to the lens in 30.5 per cent, to the iris in 10.5 per cent, to the retina in 8.5 per cent, to the cornea in 10.5 per cent (edema, infection, erosion) to ruptures of the sclera in 9.5 per cent and of the choroid in 8.5 per cent (with rupture of the ro-

tina in 1 case resulting in hemianopia). Contusions of the optic nerve occurred in 5.5 per cent. (c) Superficial wounds (17 per cent) were mostly corneal. (d) Burns (8 per cent) 60 per cent of these were caused by lime compounds. (e) Foreign bodies which passed into or through the eyeball occurred in 5.75 per cent, in more than one-half of the 43 cases the foreign bodies had penetrated the posterior part of the eyeball, mainly in the sclera, and the lens was injured in at least 50 per cent of the cases; in 10 cases the foreign body remained in the anterior part of the globe. (f) Injuries of the orbit (4.75 per cent) consisted mainly of hemorrhages or fractures. (g) Injuries affecting the cranium associated with involvement of the visual apparatus accounted for 1 per cent. (h) Cases in which trauma precipitated detachment of the retina, hysterical blindness, or glaucoma accounted for 4.25 per cent.

Observations on treatment and long-term histories. Prompt local and general (sulfonamides and penicillin) treatment is the primary consideration in eye injuries.

Results of treatment of lenticular affections were more satisfactory in cases in which every effort was made to combat a rise of tension and irritability of the iris and in which operation was deferred until a later date.

There were 43 cases of penetrating foreign bodies. In 7 of the patients the foreign body had passed through the globe; in 3 the eyes had to be enucleated, 3 patients had very reduced vision, and the seventh patient had practically normal vision.

Of the 60 cases in which the foreign body had lodged in the anterior segment, magnet or forceps extraction yielded satisfactory results in 8 cases. Of 25 cases in which the foreign body had lodged in the posterior segment, ultimate enucleation of 16 eyes was necessary. The posterior route of extraction is considered best.

There were 7 cases of sympathetic ophthalmia. These represented about 1 per cent of all penetrating wounds and ruptures of the globe. The average time of development after injury was 7 weeks.

There were 3 cases of eclipse blindness and ulceration of the cornea following a splash of tar (creosol).

An analysis of 9 cases of optic nerve involvement revealed reduction of vision in 6 instances. There were 3 cases of subdural hematoma. In the author's series and all 3 patients were subsequently operated upon.

Medicolegal aspects of industrial injuries. A variety of problems, including malingerers, present themselves and must be considered.

JOSEPH A. ZIEGLER, M.D.

Peripheral Positional Nystagmus. P. G. GRILLON. *J. Lar. Otol. Lond.*, 1948, 62: 47.

Peripheral positional nystagmus is defined as a spontaneous nystagmus, not constantly present, but appearing when the head takes a special position in space. It is frequently found in disease of the cen-

tral nervous system especially the posterior cranial fossa (tumors of the brain etc.) Many cases have been described in which the nystagmus was caused by the peripheral labyrinth peripheral positional nystagmus.

In the author's experimental investigations positional nystagmus is divided into two groups (1) central positional nystagmus and (2) peripheral positional nystagmus.

Central positional nystagmus In rabbits poisoned with alcohol the nystagmus was dependent on the position of the head in space, it developed in both lateral positions and continued as long as the position of the head remained the same. It maintained a constant character the nystagmus of the upper eye with the quick component towards the nose the nystagmus of the lower eye with the quick component towards the ear.

In addition to the horizontal nystagmus rotatory positional nystagmus also was observed. This nystagmus was absent after bilateral extirpation of the labyrinth.

Similar experiments with quinine were conducted in rabbits. Positional nystagmus was a frequent though not a constant phenomenon.

Some investigators considered the cause as central—presumably toxic damage of the vessels of the brain. Experimentally a positional nystagmus was demonstrated even after bilateral elimination of the labyrinth and extirpation of the cerebellum. The symptom complex of Forsman is based on allergic disorders of the circulation in the vestibular nuclear region.

Peripheral positional nystagmus Positional nystagmus was observed after centrifugating guinea pigs when the head took a special posture. In the development of a positional nystagmus the importance of changes especially hemorrhages and inflammatory processes in the perilymphatic space was stressed.

In a series of 7 cases of positional nystagmus the condition followed a radical mastoid operation in 3 cases trauma of the labyrinth in 1 case an acute otitis media with mastoiditis in 2 cases and acute exacerbation of chronic suppurative otitis media in 1 case. Most patients complained of giddiness some times with sickness and vomiting. Some patients indicated which position of the head they avoided to prevent provoking an attack of vertigo and vomiting.

The author concludes that a positional nystagmus of peripheral origin does occur and is important in the diagnosis of labyrinthitis. That of most frequent occurrence was the so-called direction changing form. The importance of classifying the groups according to the classification of Nylen-Seifert is emphasized. This classification, which is given indicates which head posture develops.

Direction-changing positional nystagmus Positional nystagmus developed especially in the lateral positions in 5 cases (a) in both lateral positions the nystagmus beats with the quick phase to the lower

ear, (b) in both lateral positions the nystagmus beats with the quick phase to the upper ear.

Direction-decided positional nystagmus In one case the patient developed no nystagmus when in the sitting position in dorsal position there developed right and left lateral position nystagmus—R. This type was also found by Klestadt.

Irregular positional nystagmus Irregular positional nystagmus did not occur in this series of patients.

JOSHUA ZUCKERMAN M.D.

The Surgical Treatment of Pterygium. ARTHUR D OUBRAIN *Brit J Ophth.* 1948, 32 65

The author believes that pterygium is due primarily to irritation and that only secondarily is it a degenerative process. He cites the fact that hot climate and low humidity predispose to the formation of both pterygium and pinguecula. He believes also that pinguecula is a forerunner of pterygium since they appear similar under slit-lamp examination and the stroma or subconjunctival portion presents a similar histopathological picture of an extensive aggregation of fibrous tissue containing numerous elastic fibers and patches of amyloid and hyaline degeneration. When the contracting fibrous tissue becomes anchored at one end to the unyielding corneal tissue the looser conjunctival tissue becomes pulled toward the cornea and forms a pterygium.

The author bases his surgical technique on the hypothesis that the two conditions have the same etiology and the same histological and biomicroscopical appearance and differ only in their corneal involvement. If the essential portion of the pterygium is subepithelial then the surgical treatment must aim at the removal of the active connective tissue core and not at just transplantation of the pterygium to prevent its recurrence.

The following operation to remove the offending connective tissue is described. A horizontal incision is made in the bulbar conjunctiva above the upper border and below the lower border of the pterygium for a distance of 5 mm nasal from the limbus. The closed scissors are pushed downward through the upper incision beneath the pterygium. A small dressing forceps is then inserted in place of the scissors and is used to hold the pterygium firmly. A sharp knife is used to remove the pterygium from the cornea. A thin layer of cornea is included to be sure of removing all conjunctival tissue and its blood vessels. The apex of the pterygium is held up vertically and the whole subconjunctival portion of the pterygium as far medially as the plica semilunaris is dissected from the inner surface of the epithelial layer. The author believes that this is the real pterygium and that it should be completely removed. The free edge of the conjunctiva is trimmed enough to leave a bare strip of sclera several millimeters in width nasal to the limbus. This area becomes covered with conjunctiva but not until after the cornea has had time to heal. With the use of this surgical technique there have been no recurrences over a 7 year period.

ROGER H. JOHNSON M.D.

Lid Repair and Reconstruction SIMON A. FOX.
Am J Ophth. 948, 31:317

Displacement of the canthi is not of common occurrence. Usually there are complications because trauma causing the condition is extensive and severe, the eye being lost.

Three cases are reported. In case 1 there is an empty socket with severe cicatricial lagophthalmos, dislocation of the lateral canthus upward to an angle of 45 degrees. In case 2 a vertical scar runs across the forehead displacing the medial canthus downward, and in addition creating a cicatricial epicanthus; the socket is also empty. In case 3 there is a wide linear scar running through the medial canthus which is displaced downward 8 mm.

The same principles of repair are applied in all cases. The canthal ligaments, or their equivalents are thoroughly mobilized and reattached to their natural anatomic points of insertion. When the medial canthal ligament is displaced, it is usually necessary to sever the attachment of the lateral canthal ligament (Wheeler). Another principle governing the technique of repair is that of making a Z-plasty: two arms of which include the displaced canthus. The transposition of the flaps gives a double advantage: firstly it prevents the danger of healing scar tissue pulling displacing the canthus again and secondly it supplies skin tissue where it is most needed from adjacent sites. The residual epicanthus in case 3 is corrected by means of a double Z-plasty (Blair).

The importance of the points of attachment of the canthal ligaments is stressed. The lateral canthal ligament inserts into the orbital tubercle on the zygomatic bone which is behind the lateral palpebral raphe of the orbicularis, lying deeper than the medial ligament, and does not form a prominence as does the latter. The medial palpebral ligament attaches to the frontal process of the maxilla beyond the anterior lacrimal crest and forms a prominence which is normally easily palpable. Despite this, the attachment is deeper than one would suppose. This is important, especially when the canuncle has been preserved for unless the canthus is replaced in its original position at the lacrimal crest the canuncle and the semilunar folds are hidden and the optimum cosmetic result has not been obtained. In the repair procedure, all fibrous tissue must be resected to reduce as much as possible the displacement by scar tissue contraction. The ligaments must also be firmly anchored in place. MICHEL LOUVALIAN, M.D.

Statistical Study of Retinal Detachment CARL H. BACLEY *Am. J. Ophth.* 948, 3:85

The material on which the present survey is based consists of 304 consecutive cases of retinal detachments in patients operated upon in the Wilmer Ophthalmological Institute during the period between 1937 and 1944. There were 246 phakic and 58 aphakic eyes. Sixty-eight patients had detachments of at least three quadrants and 25 had detachment of the entire retina. 53 patients had detach-

ment occurred more than 6 months before operation. The majority of patients were between the ages of 40 and 60 years. Approximately 40 per cent of the phakic detachments were myopic, but myopia was not a significant factor in aphakic separations. Degenerative changes in the vitreous are a more important factor in phakic than in aphakic eyes (45 per cent versus 20 per cent). After cataract extraction, the onset of detachment was longer than 6 months after operation in 55 per cent of the patients, and longer than 2 years in 36 per cent. Trauma is somewhat more common in a phakic than in a phakic eye. Retinal perforations in aphakics were observed less frequently than in phakics and lead to the view that degenerative changes in the retina precede retinal perforations and subsequent detachments.

The discouraging prognosis of detachments associated with nevi and glial bands in the vitreous is well known. However 5 per cent of the phakic and 1 per cent of the aphakic eyes had a positive aqueous ray at the time of operation. The preoperative clinical findings determining favorable and unfavorable prognosis, follow.

1. The prognosis was poorer after the age of 60 in phakics.

2. Increasing myopia was directly related to the poorer operative results.

3. Thirty five per cent of the detachments in aphakics were mechanically successful after operation as compared to 51 per cent in phakic eyes.

4. When present in aphakic eyes, persistent vitreous opacities have a detrimental effect. To 16 per cent successful reattachment when no vitreous was lost at the time of operation as opposed to the 37 per cent of reattachments, when no vitreous loss occurred by the aphakic eyes.

5. In the presence of positive aqueous ray in phakic eyes there have been 11 failures in 25 operations.

6. The duration of the detachment before operation vitally affects the prognosis. In aphakics, after 3 months only 1 reattachment followed 11 attempts, against 37 per cent of successes if operation was performed within 3 months of the onset of the detachment. Delays in phakics are apparently of less concern except for the danger of involvement of more or less extensive areas.

7. In the phakic cases it makes little difference in the eventual result whether the detachment is in the upper or the lower half but in all 7 cases with detachments nasally the results were unsuccessful. However an operative success of 34 per cent was obtained in complete detachment nasally including the nasal half. In aphakics there was no difference in operative results between temporal and nasal detachments.

8. Operative results were significantly poorer when no retinal perforation was found. The location of the perforation had no effect on the operative result.

9. There has been 50 per cent operative success in patients in whom the preoperative tension was 29 mm. Hg (Schiotz) or over.

10 The present series shows no difference in retinal elevation at the time of operation. It is concluded that a wide gap between the retina and choroid is no insuperable barrier to success.

The author compares and evaluates the results of various operative techniques. In the course of years gratifying improvement has been made in operations for retinal detachment. As a result of the increasing success many operations are advised now that would not have been recommended in the rather recent past. With the beginning of penetrating diathermy success rises sharply for both phakic and aphakic. A 60 per cent success following the first operation was shown in 5 straight thermophore operations while a successful result occurred after a second operation in 1 case, raising the success rate to 80 per cent. The amount of subretinal fluid obtained at operation has little effect on final reattachment. When diathermy punctures were made both before and after the escape of subretinal fluid the effect was about the same as when the punctures were performed only before the escape. In detachments of comparable size equally successful results were obtained when extensive areas were coagulated and when coagulation was limited to the area around the hole or one quadrant. When three quadrants were detached the best mechanical results were obtained when the area of coagulation was relatively limited. The position of the retina following evacuation of subretinal fluid was found to be of utmost importance in determining final reattachment. In 166 phakic cases in which the retina was found flat or only slightly elevated at the end of operation successful reattachment occurred in 60 per cent. However in 72 cases in which the retina remained greatly elevated at the end of operation successful results were obtained eventually in only 20 per cent. In 37 cases of aphakia in which the retina was flat or only slightly elevated at the end of operation successful results were obtained in 43 per cent whereas in 16 aphakics with greatly elevated retina at end of operation success was obtained in only 6 per cent. The importance of leaving the retina relatively flat at the end of operation has been emphasized. In many cases revealing persistence of marked elevation of the retina after the evacuation of subretinal fluid saline has been injected into the anterior chamber or vitreous of aphakic eyes. In phakics in which the retina failed to fall back properly after the withdrawal of subretinal fluid the injection of saline through the attached portion resulted in success (46.7 per cent) an improvement but not a significant difference from those cases in which the retina was allowed to remain elevated. Injection of saline through a quadrant in which the retina was detached gave poor results (only 1 cure in 11 attempts). The intraocular injection of saline by any route in aphakics resulted in significant improvement over those in which the retina remained greatly elevated at the close of operation. No serious complication followed the intraocular injection for example infection, cataract, hemorrhage or persistent vitreous opacities.

The retinas of about 41 per cent of phakic detachments were successfully reattached on the first attempt. Of the 145 failures less than half of the patients had second operations with success in 26.4 per cent. This shows that one failure is by no means final and offers a strong incentive to reoperate. For phakics the incentive exists for even as many as 5 operations. Reoperations have raised the final percentage of success to 50.3 per cent. In aphakia only one operation after failure is advised.

MICHEL LOUFRAN M D

Saline Injections in Retinal Detachment EDWIN G. GRANTON JR. and JACK S. GUYTON *Am J Ophth.* 1945 31: 299

The early injections of saline into the vitreous cavity given with the thought of forcing the retina back against the choroid were usually doomed to failure because the retinal holes were not sealed. In the modern surgical treatment of retinal detachments it is well recognized that not only an artificial choroid must be created to close the retinal holes but that retinal fluid must be drawn through openings in the sclera if a high percentage of reattachments is to be attained. These openings are most frequently made by means of diathermy puncture or trephine and should remain patent a number of days. The postoperative physiologic formation of aqueous usually counted upon to fill the vitreous cavity, displacing the subretinal fluid and forcing the retina back into contact with the choroid. In eyes with high elevation of the retina and slow formation of aqueous the scleral openings may close before the desired result is obtained or else the areas of artificial choroiditis are no longer active enough to close the retinal holes by the time the retina arrives in contact with the choroid. In such cases it is now common practice either to remove subretinal fluid at the time of operation or to inject air into the vitreous cavity in order to force the retina back at the time of operation.

In tables showing the percentages of reattachments in cases in which operations were performed with or without injection of saline into the vitreous the result appears approximately the same. However these figures can be quite misleading as those eyes receiving saline injections were those with much the poorer prognosis for reattachment—and the finding of equal results in groups with or without saline would indicate that the injections were of real value. Saline injections into the vitreous were performed only in those eyes in which the retina was still markedly elevated after diathermy and adequate openings had been made between the subretinal space and the outside of the sclera.

The technique of saline injection in an aphakic eye is performed by making a tiny slanting opening through the cornea at the limbus with a Zeigler knife introducing a 27 gauge hypodermic needle with an attached syringe filled with normal saline solution through the tract made by the knife and injecting saline into the anterior chamber.

For injections into phakic eyes, a 27 gauge needle with attached syringe filled with saline is inserted through the conjunctiva, sclera and pars plana of the ciliary body in whichever quadrant the retina is most elevated. As the needle is inserted diathermy current is passed through it. The needle is inserted in such a direction that the point slants backward from the lens. Saline is then injected directly into the vitreous cavity. The injection is slow and forces the subretinal fluid out through the scleral punctures and the retina back into place in contact with the choroid. A sufficient amount is injected to flatten the retina as completely as possible.

Saline injections do not produce inflammation. A disruption of the vitreous is obtained but all eyes with marked retinal separation have already an extensive disorganization of the vitreous. Saline is preferred to 'vitreous' from other eyes, as it will not produce undesirable opacities. Saline is, also preferred to air as it does not hinder ophthalmoscopic examination. MICHAEL LOUVALLOU, M.D.

EAR

"Permanent" Deafness Due to Gunfire G. REM.
J. Laryngol. Lond. 1918 6 76.

Audiometric and clinical studies were made of 16 artillerymen who had no evidence or history of ruptured tympanic membranes or middle ear disease. The mean average hearing loss of the group was 10.2 decibels. 20 per cent of the men had an average loss (5.1 to 8.1%) of greater than 20 decibels and 8 per cent had average losses of greater than 30 decibels through the speech range. Fifty per cent of the men had peak losses of greater than 30 decibels in the worse ear. Most of the damage occurred in the first or second year of service. Among the various types of audiometric curves was every gradation from an abrupt to a gradual type of high tone loss. The shapes of the hearing curves in early temporary traumatic deafness were also variable and differed in no way from those in cases of permanent deafness.

No evidence was found that "abrupt" loss characterizes deafness following a single severe detonation.

JOHN R. LINDSAY M.D.

Foreign Body in the Eustachian Tube. Report of a Case ROBERT C. McNAUGHT *Laryngoscope* 1918, 58 67

The author presents the case of a welder who suffered intense pain and sudden deafness when a spark flew into his left ear. At the first aid clinic the ear was ill-advisedly syringed with water. Purulent drainage followed. Four months later roentgen examination revealed a small metallic foreign body in the tympanic part of the eustachian tube. The piece of slag was removed by catheter inflation of the eustachian tube. Purulent drainage stopped immediately and the perforation of the tympanic membrane was much smaller when last seen. one month later JOHN R. LINDSAY M.D.

Some Experiences in the Surgery of Labyrinthitis. PHILIP READING. *Guy Hosp Rep* Lond 1917 96 75.

Of 51 cases of labyrinthitis complicating mastoiditis, cholesteatoma was found to be present in 40. In most of the cases the portal of entry was found to be through a fistula in the horizontal semicircular canal. Erosion of the facial canal was seen in 39 of these cases and facial paralysis was present in 11.

Six cases were encountered in which there had occurred "silent death of the labyrinth." In these cases there was no history of deafness although labyrinth function was completely gone. The final destruction of the labyrinth may have followed a low grade, insidious serous labyrinthitis. Destruction may be so slow in these cases that the vestibular nuclei have ample time to adjust the body's posture and balance. It is possible therefore, for a latent diffuse suppurative labyrinthitis to be present in a patient in the absence of vertigo. Labyrinthotomy has been considered indicated to supplement radical mastoidectomy in these cases in order to prevent an occasional death from postoperative meningitis. Careful evaluation of labyrinth function must be done before surgery is performed even though there are no symptoms of labyrinthitis.

Of 56 patients with labyrinthitis, 13 developed meningitis, 13 developed brain abscess, and 4 had lateral sinus thrombosis. Eleven of the patients with labyrinthitis and meningitis recovered following mastoidectomy, labyrinthotomy, and transabyrinthine drainage of cerebrospinal fluid through the internal auditory meatus. All patients were treated before penicillin was available in adequate amounts. The effect of therapy with sulfonamides and antibiotics may alter indications for surgery of the labyrinth.

Labyrinthitis not infrequently may cause cerebellar or temporosphenoidal brain abscess.

Four pertinent case histories are presented.

NOSE AND SINUSES

Plastic Repair of the Obstructing Nasal Septum. SAMUEL FORDON JOSEPH G. GILBERT A. GILBERT SILVER, and VITO RUTCH STRAUSS. *Arch. Otolaryng.* 1918 47 7

The original method of correcting septal deviation was accomplished by orthopedic readjustment, and heavy instruments were used to fracture both the bony and cartilaginous septum. This method was not successful in holding the septal cartilages in place and the operation devised by Killian in 1899 became the one of choice by most rhinologists. This operation however has several weaknesses, such as the belief that removal of the anterior and inferior portion of the septum causes saddle nose deformity.

The authors believe that the septum does not offer support to the nasal pyramid but acts only as a reserve factor. It follows then that saddling of the dorsum and distortion of the tip subsequent to a too generous resection of the septum result only from

tensions developing from the cicatricial pull of the deskeletonized septal membranes—not from lack of support. Therefore any part of the septum may be removed without fear of subsequent deformity provided precautions are taken to neutralize these traction forces.

With these concepts in mind in the Fomon technique for the correction of septal deformities the septum is transfixed, and the cartilage is freed from the mucoperichondrial membrane and removed. In the meantime a bed has been created in the columella and a portion of cartilage inserted into and held firmly in, this bed by sutures.

The Galloway operation is described as being applicable only to the most caudal displacements of the septum. With this technique the septum is not transfixed but the membranous septum is cut throughout its extent on the right side followed by elevation of the mucoperichondrium on each side and the septal cartilage is removed with scissors or a swivel knife. The columella is corrected in much the same way that correction would be accomplished by the Fomon technique.

In septal obstructions associated with external nasal deformity satisfactory results depend upon the sequence of the operative steps as well as on the care with which each step is carried out.

PHARYNX

Juvenile Nasopharyngeal Angioblastoma. HAYES MARTIN, HARRY E. ENGLISH, and JULES C. ABLE. *Ann Surg.*, 1948, 127: 513.

All 29 cases of juvenile nasopharyngeal angioblastoma observed by the authors during a period of twenty years occurred in pubescent males. Reports in the literature of the occurrence of this tumor in young children, adults, or females are very likely mistaken diagnoses. The selectivity for males and spontaneous regression with the appearance of full sexual development strongly imply a sex-endocrine relationship for this tumor. In the tumors of younger subjects angiomatous elements predominate but as sexual maturity is approached the fibrous tissue stroma replaces to a large degree the vascular elements. In normal individuals mucous membrane hyperemia is known to result from estrogen stimulation. The hypothesis is advanced that this tumor may result from estrogen stimulation of the vascular tissue of the nasopharynx in young males having a hormonal imbalance. Over one half of the cases presented evidence of under-development of secondary sexual characteristics.

The initial symptom is nasal obstruction. Repeated nasal hemorrhages usually occur. Facial deformity results from large nasopharyngeal fibromas.

The tumor is anatomically and clinically benign, regresses spontaneously with sexual maturity and causes no further trouble. The real hazards result from the complications of hemorrhage, sepsis, facial deformity and the effects of overaggressive attempts

at complete eradication by surgery or radiation. Treatment consists only of control of the tumor until regression takes place.

Severe epistaxis is best controlled by ligation of both external carotid arteries. Prolonged nasal packing results in ulceration and sepsis.

Sex hormone (testosterone propionate) therapy was used in several cases with gradual elimination of the tendency to bleed, however regression of the tumors was not noted. In 2 cases puberty was hastened by the use of androgens and in these cases roentgen irradiation appeared to induce a more ready regression of the tumor. Roentgen therapy is indicated in bleeding nasopharyngeal fibroma. These tumors are moderately radiosensitive. Radium therapy has its place as supplemental treatment to roentgen irradiation and following surgery. Twenty years ago 2 patients were given a large dose of interstitial radiation which was followed by osteonecrosis of the sphenoid bone, brain abscess, and death.

Large tumors with marked facial deformity and progressive destruction of the maxilla and other adjacent bony structures by pressure necrosis should be partially removed surgically. A transmaxillary approach may be used. Complete removal is impossible.

Several methods of treatment should be combined as a rule.

An analysis of data indicates that smaller doses of interstitial and roentgen radiation will effectively control symptoms if the patient is receiving continued and adequate endocrine therapy.

JOHN R. LEIDY, M.D.

NECK

Tuberculous Cervical Adenitis. HAMILTON BAILEY. *Lancet Lond.*, 1948, 1: 513.

This is a report of 20 years' experience with cervical tuberculosis encompassing from 1,300 to 1,500 operations. The author points out that the therapeutic pendulum has swung from conservative measures to surgical intervention to x-ray therapy and heliotherapy and now back again to surgical measures.

Cervical tuberculous adenitis progresses through four stages if not halted by surgical intervention. Stage 1—breakdown of tuberculous lymph node with the pus limited by the fibrous capsule of the node or nodes. Stage 2—in many cases in due course the envelope bursts and the pus comes to occupy that confined space limited by the deep cervical fascia. Stage 3—after weeks or months the dense deep cervical fascia becomes eroded and the pus swells into the commodious compartment beneath the yielding superficial fascia. This forms a collar button abscess, which at times may have a long stem. Stage 4—the superficial abscess steadily enlarges until the skin over it becomes inflamed. The abscess bursts and a draining sinus results.

Bailey does not favor the aspiration of these abscesses as advocated by Calot as this gives good

Fig. (Bailey). Scheme of general principles of operative treatment of tuberculous cervical adenitis.

results only when the patient is under constant supervision and the improvement is depressingly slow. In the past 8 years he has had 300 cases, so treated referred to him because of failure of this treatment.

Nor does he favor curettage. It is not only inefficient, but dangerous surgery to scoop down blindly in a fistula in the neck where it is filled with large vessels. Such a procedure is the antithesis of the highest attainment of surgery which is to aid Nature.

The operative technique will be influenced by the group of nodes involved and the presence or absence of skin involvement. Knowledge of the anatomical grouping of the cervical glands is a prerequisite of surgery which must be directed only at those involved.

The author believes that tonsils, adenoids, and carious teeth are the main portals of entry by which the tubercle bacilli enter the cervical lymphatic system. Therefore tonsils and adenoids should be removed and necessary dental care undertaken. Tonsils and adenoids should be removed after neck surgery as secondary involvement from pyogenic infection makes the cervical surgery more difficult.

The accompanying diagram gives the broad outline of Bailey's views drawn from his experience with tuberculous cervical adenitis.

EDMUND R. DOROGUIN, M.D.

Complementary Extirpation of Lymph Glands.
Critical Study Indications, and Technique (Os
esvaseamientos ganglionares complementares. Es-
tudio crítico indicaciones técnicas) ALVARO RODRIGUEZ. *Arg. pat.*, 943, 14 7

At a time when the primary cancer of the lip was still curable metastases in the lymph glands of the neck were found by the author in 20 per cent of his cases while of his patients with cancer of the tongue which was still curable 65 per cent presented metastases in the lymph glands of the neck. The greater frequency and precocity of invasion of the lymph glands in cancer of the tongue is due to the structure and mobility of the affected organ which

accelerate the lymph flow. This fact has been demonstrated by the author by animal experimentation.

The author studied the topography of the lymph glands most frequently invaded by the cancer originating in the lips or the tongue, in specimens removed en bloc. Histopathologic studies showed that with the exception of a few instances with retrograde or contralateral metastases the most frequently affected glands were the submaxillary and submental. An invasion of the jugular or spinal lymph glands was never observed in cancer of the lip.

In lesions of the anterior and middle third of the tongue, chiefly the submental and submaxillary and less frequently the jugular glands were invaded. In lesions of the posterior third of the tongue the author was able to establish the integrity of the submental glands, but occasionally he found invasion of the submaxillary glands, while the jugular glands were invaded in each instance. The spinal chain and the retrosternal glands were sometimes invaded. Lesions of the anterior third and less frequently those of the middle third strictly confined to one side, may produce bilateral metastases. As a rule lesions of the posterior third of the tongue confined to one side produced metastases only on the corresponding side.

Carcinomatous cells in the lymph glands are very radioresistant and therefore an implantation of radium needles is preferable to x-ray treatment. However good results may be expected only if metastases are confined to irradiated glands. It is evident that such glands cannot be easily identified before the application of radium. X-rays have only a sclerosing effect on metastases in the neck. Generally speaking surgery is the method of choice in the treatment of metastases in the neck, except in cases in which the primary lesion is located in the palate or belongs to special types, such as lymphoepithelioma or cancer of the intermediate type. A surgical intervention is contraindicated only in the presence of insurmountable technical difficulties.

In cancer of the lip a dissection of the lymph glands should be undertaken only if they are palpable and suspicious. On the other hand, in cancer of the tongue the lesion is very limited and detected in the early stages a prophylactic dissection of the glands is always indicated.

Dissection should not be undertaken until castration of the primary lesion has been accomplished because in the majority of cases a glandular recurrence is the consequence of the recurrence of the primary lesion.

The author describes a technique which allows a nearly complete removal of the chain of the lymph glands of the neck with preservation of the spinal nerve and the sternocleidomastoid muscle. The common or internal carotid artery and the pneumogastric nerve must be ligated. Two incisions are made: one parallel to the lower jaw on the involved side and the other extending from the mastoid process to the clavicle parallel to the sternocleidomastoid.

mastoid muscle. Contrary to the opinion of several American writers, the author advocates the resection of the anterior belly of the digastric muscle.

JOSEPH K. NARAT, M.D.

Carotid Body Tumors. WILLIAM S. MACCOMB, *Ann Surg* 1948 127 269

Carotid body tumors are rarely seen on the surgical services of most hospitals. A survey of the literature reveals reports of nearly 300 tumors of this type since the first case was reported in 1903.

The exact function of the carotid body is still not definitely established. The most recent thought is that they contain chemoreceptors which respond to chemical changes in the blood. The 1941 report of the Mayo Clinic indicates that the function, whatever it may be, is negligible since both carotid bodies can be enucleated without any manifest symptoms.

Carotid body tumors occur most frequently in the third and fourth decades of life with no predominance in either sex.

The usual symptoms are a mass or lump in the neck which has often been present for several years or the presence of a pharyngeal mass. The patient frequently presents himself because of a noted increase in the size of the mass. Involvement of the vagus nerve, cervical sympathetic chain or hypoglossal nerve has been observed.

The diagnosis of carotid body tumors is difficult; tumors of this type are rare, but must be considered. The authors recommend aspiration biopsy.

Most authors agree that carotid body tumors should be removed surgically, yet the necessity for ligation of the common and internal carotid arteries occurs so frequently that were it possible to be certain of the benign nature of the tumor, it might be better to refrain from this procedure, because of the high postoperative mortality. The possibility of a benign tumor later becoming malignant must be kept in mind, however.

Mortality rates for surgical excision of carotid body tumors with ligation of the common and internal carotid arteries, are reported from 0 to 100 per cent. Such results demand careful consideration before an operation is undertaken which may require resection of the carotid arteries. Postoperative disabilities are estimated to be as high as 83 per cent. They consist of temporary or permanent hemiplegia and the effects of injuries to the cervical sympathetic, hypoglossal or vagus nerves.

In the author's series of 10 cases, the carotid body tumor was resected without injury to the arteries in only 3 instances. In the other 7 cases it was necessary to include the carotid arteries in the resection of the tumor. There were 4 postoperative deaths. Hemiplegia preceded death in each instance. The postoperative mortality rate for the 7 patients requiring removal of the carotid arteries was 58 per cent. The mortality rate for the total group of 10 patients was 40 per cent.

Fatalities following carotid ligations are usually the result of insufficient collateral cerebral circula-

tion or an ascending thrombosis of the internal carotid artery. In the former hemiplegia occurs immediately and in the latter from 30 to 36 hours postoperatively.

The Matas test should be utilized to determine the collateral cerebral circulation and if necessary a partial occlusion should precede total occlusion and removal of the tumor.

Ascending thrombosis possibly can be prevented by ligating over a strip of fascia to prevent internal damage, and by the use of heparin postoperatively.

It is difficult to get adequate biopsy material to enable the pathologist to determine whether or not the tumor is malignant. If one could be certain that a carotid body tumor was benign it might be wise to keep the patient under observation and refrain from the use of surgery except in cases in which the increasing size of the tumor is believed to be causing symptoms of pressure.

EDMUND R. DONOHUE, M.D.

Gastric Acidity in Thyrotoxicosis (*La acidimetria gástrica en la tircotoxicosis*) JUAN C. PLA, C. MUÑOZ MONTAÑANO and DANIEL MUÑOZ. *Arch. Med.* 1947 30 446

The gastric juices of 30 patients having various types of thyrotoxicosis were analyzed. Of these 16 showed anachlorhydria (43.3%), 9 hypochlorhydria (30%), 3 normal chlorhydria (15%) and a hyperchlorhydria (6.6%). It was found that when the basal metabolism was above 50 per cent, anachlorhydria was more frequently observed and was present in those who never had treatment for hyperthyroidism or had treatment for only a short time. The other conditions were seen in patients who were treated from 6 months to several years. Gastroscopic examinations were made on 9 patients—2 with normal acidity, 1 with hyperchlorhydria, 2 with hypochlorhydria, and 4 with anachlorhydria. All showed normal mucosa except one who had a superficial gastritis.

These observations led the authors to conclude that anachlorhydria of the thyrotoxic patient is purely a functional disturbance.

STEPHEN A. ZIEHL, M.D.

Results of Prolonged Medical Treatment of Hyperthyroidism with Thionorea T. S. DAKOWSKI, E. B. MAN, J. R. ELKINGTON, J. P. PETERS, and A. W. WINKLER. *Am. J. Med. Sc.*, 1948, 215 123

To determine the efficacy and advisability of prolonged medical treatment of thyroid overactivity 118 hyperthyroid patients were given thionorea usually together with a strong solution of iodine. The authors state their patients reported subjective improvement after from 1 to 2 months of the start of thionorea therapy. When an optimum therapeutic regimen of 75 to 210 mgm daily is employed a favorable clinical response follows with decreased metabolism levels, a cancellation of body weight losses and a disappearance of the tachycardia. The concomitant use of a strong solution of iodine en-

hances the response. The advantages and disadvantages of treatment of hyperthyroidism are discussed.

The authors conclude, from their series of 80 patients who were under treatment for from 6 months to over 2 years, that thyroid overactivity can be controlled for long periods by thiourea and iodine with a minimal incidence of toxic reactions. The authors report occasional gastrointestinal distress and in 2 patients, drug fever. In a small number of patients the hyperthyroidism seems to have disappeared. W. FOSTER MONTGOMERY, M.D.

Lingual Gutter. EMIL GOSTER. *Ann. Surg.* 1948, 27: 291

A critical study of 3 cases of lingual gutter that came under the author's care is presented.

Previously Montgomery presented the following criteria of authenticity for such cases: (1) the examination of the specimen removed should reveal thyroid gland tissue, or in lieu of this requirement, (2) thyroid insufficiency should supervene following removal of the nodule, and (3) the lesion should appear in the substance of the tongue between the epiglottis and the circumvallate papillae.

At least 90 per cent of patients with lingual gutter suffer from symptoms of pressure and obstruction such as dysphagia, dysphonia, and dyspnea. Less frequently reported symptoms are fullness and a feeling of tightness in the throat. Authoritative instances of hyperthyroidism have not been reported in cases of lingual thyroid. Pain is uncommon. Thyroid insufficiency has been reported in about 15 per cent of the cases, and the only physical characteristics seen are those associated with thyroid insufficiency; otherwise these patients are singularly free from associated developmental anomalies.

These tumors vary in size from that of a pea to the size of an orange. They are usually globular, the surface smooth or somewhat lobulated, the color red to dark red. Surface vessels usually indicate a fair degree of vascularity. The lesions are usually median in position, at or immediately posterior to, the foramen cecum and are attached by a broad base. Some are superficial, others penetrate into the deep substance of the tongue. The tumors reported resemble, in many ways, the appearances often seen in cervical adenomatous goiter. However the majority resemble more nearly the normal thyroid tissue. Carcinoma has been reported, but is uncommon and has never been reported in a female patient. Many of these show the microscopic picture of the fetal adenoma and thus are capable of producing multiple types of epithelial overgrowth, suggestive of malignancy. This has made it difficult for the pathologist to make a final diagnosis on a biopsy per se. The clinical course and involvement of regional nodes must be considered for a final opinion.

Surgery has been resorted to because the symptoms are mainly those of laryngeal and pharyngeal obstruction. The tongue is withdrawn by traction sutures and the mass raised with a finger in the pharynx. Transfixion sutures are placed before an elliptical incision is made, which leaves a little thyroid tissue on either side and the posterior pole. The transfixion sutures are tied to control hemorrhage and additional sutures are placed as required. Some thyroid tissue must be left as two-thirds to three-fourths of these patients may be without thyroid tissue in the normal location in the neck. If hypothyroidism persists or develops, it is controlled with thyroid extract.

A review of the pertinent literature has also been given. EDWARD R. DOMENICA, M.D.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS; CRANIAL NERVES

Experimental Observations in the Treatment of Craniosynostosis. FRANC D. INGRAHAM, DONALD C. MATSON, and EDEY ALEXANDER, JR. *Surgery* 1948 33 353

In craniosynostosis there is a premature sealing of the cranial sutures causing mechanical compression of the brain with limitation of its growth and subsequent neurological dysfunction. It is believed that the current surgical measures used to combat this condition are in general, unsatisfactory in the first months of life because of the rigid reformation and fusing of bones after the operative procedure. The authors have endeavored to devise a method of producing and maintaining artificial channels in distribution similar to the normal sutures which have prematurely fused.

Experiments were carried out on 11 dogs and 16 monkeys to study the reaction of inert foreign substances placed in channels of the cranial bones. Burr holes were made in the frontal and posterior parietal regions bilaterally about 1.5 cm. from the midline. These were then joined on either side by the Gigli saw and trimmed with a chisel so that a 2 mm. gap remained on both sides for a distance of 2.5 to 3 cm. Drill holes were made about 3 mm. from the edge of the saw cut so that 4-0 silk sutures could be passed through the cranium and the experimental substance held in position. The various materials were interposed on the right side, the left served as a control.

Specimens were studied at intervals of 32 to 315 days and the gross appearance of the foreign material, the bone, the scalp, and the underlying dura was observed. Histological studies were made of cross sections of saw cuts containing each substance and its corresponding control. When fibrin film was used bony union occurred over the material in from 6 to 7 months. With the use of oxycel the authors were able to obtain solid fibrous union which was as strong as the early bony fusion on the control side. Around the interposed tantalum there was no new bone formation, but its weight and radio-opacity are undesirable features. Bone did not form over lucite but the material was deemed unsatisfactory because of its rigidity and brittleness. Polyethylene exhibited the most desirable experimental results. It is well tolerated by the tissues and can be procured as hollow flexible tubing which is the form in which it was employed here. There was no new bone formation and flexibility of the tubing persisted even after it was embedded in tissue for over 9 months.

The authors have included numerous excellent illustrations to demonstrate their findings. Clinically they have used polyethylene successfully in 6 infants suffering from craniosynostosis.

RICHARD C. SCHNEIDER, M.D.

Cerebral Arteriography. I. S. WECHSLER and S. W. GROSS. *J. Am. M. Ass.*, 1948 136 517

The authors stress the fact that ruptured aneurysms are not the only cause of subarachnoid hemorrhage. They report 10 cases in which arteriography was performed in the acute or subacute phase after hemorrhage. In 6 cases vascular malformations were demonstrated and in only 4 cases were aneurysms present. No serious complications were incurred as a result of arteriography. Because it is not radioactive and is readily excreted from the body, diodrast was used in preference to thortrast for the injections.

From their experience the authors believe that recurrent subarachnoid hemorrhages which do recover are more apt to arise from vascular malformations than from aneurysms. Death is likely to occur from leakage of aneurysms during the first or second attack unless ligation of the vessel is carried out. In this series ligation of the common carotid artery on the same side as the lesion was performed in 7 cases, 4 patients having vascular anomalies and 3 having aneurysms. There were 2 fatalities after ligation of vessels for aneurysmal bleeding; the procedure had been performed intracranially in one case and in the other the common carotid artery was ligated in the neck. Both patients were regarded as being practically moribund and the authors believed they would have died anyway.

It is deemed safer to ligate the common carotid than the internal carotid artery. If the former is done no gradual compression of the vessel is necessary; the circulation is only reduced about 50 per cent, and the complications of convulsions and hemiplegias are diminished. In one case of aneurysm the vessel was ligated intracranially and on another patient with a vascular anomaly an exploratory craniotomy was performed. Radiation therapy was used in 2 cases with vascular malformations. The authors are of the opinion that intracranial exploration usually has very little to offer in vascular anomalies and that either carotid ligation or radiation is the treatment of choice. Recurrences have not been seen in patients who have had the carotid artery ligated for vascular abnormalities, but in 2 of these patients the procedure has been performed rather recently.

The authors now feel that arteriography is simple and safe and they do not hesitate to carry out the procedure in the very acute phases of the hemorrhage so that early adequate therapy may be instituted.

RICHARD C. SCHNEIDER, M.D.

Herniation of the Cerebral Ventricles. CHARLES R. PERRYMAN and EUGENE P. PENDERGRASS. *Am. J. Roentg.*, 1948, 59 27

Spinal fluid block is likely to produce dilatation of the third, fourth and lateral cerebral ventricles.

Fig. (Perryman, Pendergram) Herniation of cerebral vent.

With the exception of anterior dilatation of the third ventricle, the herniation takes place between the incisura of the tentorium and the brain stem. For correct clinical diagnosis, it is necessary to recognize and differentiate these three varieties: (1) herniation backward of the third ventricle, (2) herniation upward of the fourth ventricle and (3) herniation downward and medially of the lateral ventricles.

Five cases of posterior herniation of the third ventricle, a case of herniation of the lateral ventricles, and a case of upward herniation of the fourth ventricle observed at the University Hospital of Pennsylvania were studied. The ventricles and their various recesses, with reference to normal contours seen in air studies are illustrated. The 5 cases of herniation backward of the third ventricle are described with appropriate case histories and plates. This type of herniation may occur when the cerebrospinal fluid pathway is in the fourth ventricle or aqueduct of Sylvius. This usually occurs downward under the tentorium and, when advanced gives rise to a characteristic square sign (Fig. 1).

Some of these findings were confirmed by the examination of autopsy specimens. All rarely the out-pouching of the third ventricle occurs upward over the tentorium outlining the splenium of the corpus callosum. Herniations of the third ventricle downward under the tentorium can be mistaken for herniations of the lateral ventricles if care is not exercised in examining the roentgen films. The continuity of the abnormal shadow with the third ventricle

must be established. Those of the lateral ventricle have a characteristic appearance described as "dimpling" in which the constriction of the herniation, caused by the tentorium, is clearly seen in lateral projections. This type of picture may be seen in cases in which there is an obstruction in the anterior part of the third ventricle and has been described as a subtentorial pressure diverticulum. It is not produced by lesions in the aqueduct or fourth ventricle. Obstructive conditions in the lower part of the fourth ventricle may lead to dilatation and upward herniation of the ventricle through the incisura. In these cases the continuity of the ventricles with the aqueduct can be demonstrated while in the anteroposterior views the "square sign" is not seen. The "square sign" is said to be caused by air in the herniation if the third ventricle compressed between the tentorium and the quadrigeminal plate.

It is possible that the herniations themselves cause symptoms or aggravate obstructive signs. Excision of herniations is suggested as a palliative method for short-circuiting the blocked cerebrospinal fluid flow.

ADRIAN VAN BRUGGEN, M.D.

Observations upon Patients with Penetrating Wounds Involving the Cerebellum. JOHN E. WENSTER, R. C. SCHENKEL, and J. E. LOVSTROM. *A. n. Surg.* 948, 737.

Upon analyzing 300 cases of penetrating cranial wounds observed at the Thirtieth General Hospital during World War II the authors found that

in 10 cases the lesions involved the cerebellum an incidence of 3 per cent. In 3 cases the wound of entrance was in the neck and the injury to the cranium was overlooked. The low incidence of survival of patients with wounds in the posterior portion of the cranium may have been responsible for the infrequency of hospitalized cerebellar wounds. The fact that the steel helmet provided more adequate covering of the cerebellum than of other parts of the brain may have been a significant point.

Adequate roentgenological studies were regarded as essential, and mentovertebral and occipitovertebral views were considered invaluable. Because of the possibility of the rapid development of serious complications in this region early unilateral cerebellar exploration under general endotracheal anesthesia should be performed, with excision of devitalized tissue and any large retained metallic fragments.

Five patients were operated upon at the Thirty-sixth General Hospital, in 4 cases the cerebellar injury had been completely overlooked. The 5 remaining patients had been operated upon at evacuation hospitals. The authors present 5 cases in some detail to indicate the various complications encountered. One patient had had an acute subdural hematoma which was successfully treated at the Thirty-eighth Evacuation Hospital. In 2 cases tears of the lateral sinus were serious complications at the primary débridement. A severe wound of the base with extensive damage to the cranial nerves and the internal carotid artery was another particularly difficult problem.

There was one death in the series of 10 cases a mortality rate of 10 per cent. In this patient tetanus complicated the problem of a cerebellar abscess. As final neurological dysfunction 3 other cases showed, respectively marked cranial nerve impairment with associated vascular injury unilateral deafness with peripheral facial palsy and marked visual impairment. The remaining 6 patients exhibited minimal neurological sequelae.

RICHARD C. SCHWIDLER, M.D.

Medulloblastoma Cerebelli. FRANC D. INGRAHAM
OXFORD T. BAILEY AND WILEY F. BARKER. *N. England J. M.* 1948 338 171.

Tumors of early childhood such as medulloblastoma cerebelli have been of considerable interest because of their sudden onset their poor prognosis, and their susceptibility to x ray therapy. Roentgen treatment of this condition without histological verification can be carried to dangerous extremes.

The 56 patients whose cases are discussed have been the subject of various reports by different groups of authors. The patients were seen at the Peter Bent Brigham Hospital Boston since 1930 and some had been operated on by Doctor Cushing. Seventy two operations were performed on 53 patients with an operative mortality of 32 per cent. 3 patients were considered too ill to be operated upon.

Forty-one of the tumors were midline 20 were in the pons and cerebellopontine angle, and 5 in the cere-

bellar hemisphere. In the course of 7 of 60 explorations of the posterior fossa, a tube was led from the lateral ventricle into the posterior fossa (Torkildsen's procedure). In 10 cases distant spinal or cerebral seedlings were observed and in 2 cases metastases caused paraplegia. There were 5 patients with cord bladder and 7 with severe root pains. Acute gastric ulceration was found to exist in 3 cases but in only 1 case was perforation the cause of death.

Roentgen therapy following operation is believed to be the best method of treatment, and the various dosages are set forth. A group of 15 patients received between 4,000 and 10,000 roentgens with a survival rate of 14 months. Some patients received unusually large quantities, the highest being 30,000 roentgens to the skull and spine over a period of 3 1/2 years.

As a result of their studies the authors have made two important decisions (1) that temporization with preliminary trials of roentgenotherapy are errors of judgment for the nature of the lesion can only be presumed on a statistical basis, and a child with a benign lesion may lose his chance for surgical removal during this period. (2) that Torkildsen's procedure is indicated at any time after the primary exploration of the posterior fossa when the flow of cerebrospinal fluid becomes obstructed.

ADRIEN VER BRUGGEN, M.D.

Postoperative Period of Survival of Patients with Oligodendroglioma of the Brain: Report of 25 Cases. HENRY A. SEITZ, FRANCIS C. GRANT AND JOHN H. DREW. *Arch. Neur. Psychiat. Chic.* 1947 58 710.

The classification of brain tumors rests on a fairly solid foundation. It is based on the histological picture and the history of the patient. From time to time readjustments are necessary in any scheme. A type of glioma known as an oligodendroglioma has long been regarded as being relatively benign and the survival period even after incomplete removal of the lesion is long—from 3 to 5 years.

The authors' study is based on 25 cases of oligodendroglioma observed at the Hospital of the University of Pennsylvania. In 6 cases the tumors were intraventricular and in 19 cases intrahemispheric. It is pointed out that these tumors infiltrate the brain and consequently it may be impossible to remove them completely. Thirteen tumors were sufficiently calcified to be seen in preoperative roentgenograms. 17 of the 19 intrahemispheric tumors were situated in one or the other or in both of the frontal lobes. The average duration of symptoms was 8 months in the patients with intraventricular tumors and 35 months in those with intrahemispheric tumors. Epileptic seizures occurred in 12 of the 19 patients with intrahemispheric tumors. Seeding of the ependyma adjacent to the intraventricular tumors was noted but there was no dissemination through the cerebrospinal axis.

Five of the 6 patients with intraventricular tumors survived operation and at the end of 50 months

Fig. (Perryman, Pendergrass) Herniation of cerebral vent.

With the exception of anterior dilatation of the third ventricle, the herniation takes place between the incisura of the tentorium and the brain stem. For correct clinical diagnosis, it is necessary to recognize and differentiate these three varieties: (1) herniation backward of the third ventricle; (2) herniation upward of the fourth ventricle; and (3) herniation downward and medially of the lateral ventricles.

Five cases of posterior herniation of the third ventricle, 3 cases of herniation of the lateral ventricles, and 1 case of upward herniation of the fourth ventricle observed at the University Hospital of Pennsylvania were studied. The ventricles and their various recesses, with reference to normal contours seen in air studies, are illustrated. The 3 cases of herniation backward of the third ventricle are described with appropriate case histories and plates. This type of herniation may occur when the cerebrospinal fluid pathway is in the fourth ventricle or aqueduct of Sylvius. This usually occurs downward under the tentorium and when advanced gives rise to a characteristic square sign (Fig. 1).

Some of these findings were confirmed by the examination of autopsy specimens. More rarely the out-pouching of the third ventricle occurs upward over the tentorium outlining the splenium of the corpus callosum. Herniations of the third ventricle downward under the tentorium can be mistaken for herniations of the lateral ventricles if care is not exercised in examining the roentgen films. The continuity of the abnormal shadow with the third ventricle

must be established. Those of the lateral ventricle have a characteristic appearance described as "dimpling" in which the constriction of the herniation, caused by the tentorium, is clearly seen in lateral projections. This type of picture may be seen in cases in which there is an obstruction in the anterior part of the third ventricle and has been described as a subtentorial pressure diverticulum. It is not produced by lesions in the aqueduct or fourth ventricle. Obstructive conditions in the lower part of the fourth ventricle may lead to dilatation and upward herniation of the ventricle through the incisura. In these cases the continuity of the ventricles with the aqueduct can be demonstrated while in the anteroposterior views the square sign is not seen. The "square sign" is said to be caused by air in the herniation of the third ventricle compressed between the tentorium and the quadrigeminal plate.

It is possible that the herniations themselves cause symptoms or aggravate obstructive signs. Excision of herniations is suggested as a palliative method for short-circuiting the blocked cerebrospinal fluid flow.

Observations upon Patients with Penetrating Wounds Involving the Cerebellum. JOHN E. WESSINGER, R. C. SCHROEDER, and J. E. LOYSTER. *Ann. Surg.* 94:8, 37-57.

Upon analyzing 300 cases of penetrating cranial wounds observed at the Thirty-sixth General Hospital during World War II, the authors found that

in 10 cases the lesions involved the cerebellum an incidence of 3 per cent. In 3 cases the wound of entrance was in the neck and the injury to the cranium was overlooked. The low incidence of survival of patients with wounds in the posterior portion of the cranium may have been responsible for the infrequency of hospitalized cerebellar wounds. The fact that the steel helmet provided more adequate covering of the cerebellum than of other parts of the brain may have been a significant point.

Adequate roentgenological studies were regarded as essential and mentovertical and occipitovertebral views were considered invaluable. Because of the possibility of the rapid development of serious complications in this region early unilateral cerebellar exploration under general endotracheal anesthesia should be performed with excision of devitalized tissue and any large retained metallic fragments.

Five patients were operated upon at the Thirty-sixth General Hospital in 4 cases the cerebellar injury had been completely overlooked. The 5 remaining patients had been operated upon at evacuation hospitals. The authors present 5 cases in some detail to indicate the various complications encountered. One patient had had an acute subdural hematoma which was successfully treated at the Thirty-eighth Evacuation Hospital. In 2 cases tears of the lateral sinus were serious complications at the primary débridement. A severe wound of the base with extensive damage to the cranial nerves and the internal carotid artery was another particularly difficult problem.

There was one death in the series of 10 cases a mortality rate of 10 per cent. In this patient tetanus complicated the problem of a cerebellar abscess. As final neurological dysfunction in other cases showed, respectively marked cranial nerve impairment with associated vascular injury unilateral deafness with peripheral facial palsy and marked visual impairment. The remaining 6 patients exhibited minimal neurological sequelae.

RICHARD C. SCHNEIDER, M.D.

Medulloblastoma Cerebelli FRANC D. INGRAHAM
ORVILLE T. BAILEY and WILEY F. BARKER, JR.
England J. M. 1948 838 171

Tumors of early childhood such as medulloblastoma cerebelli have been of considerable interest because of their sudden onset, their poor prognosis and their susceptibility to x-ray therapy. Roentgen treatment of this condition without histological verification can be carried to dangerous extremes.

The 56 patients whose cases are discussed have been the subject of various reports by different groups of authors. The patients were seen at the Peter Bent Brigham Hospital Boston since 1930 and some had been operated on by Doctor Cushing. Seventy-two operations were performed on 53 patients with an operative mortality of 32 per cent. 3 patients were considered too ill to be operated upon.

Forty-one of the tumors were midline 10 were in the pons and cerebellopontine angle and 5 in the cere-

bellar hemisphere. In the course of 7 of 60 explorations of the posterior fossa, a tube was led from the lateral ventricle into the posterior fossa (Torkildsen's procedure). In 10 cases distant spinal or cerebral seedings were observed and in 2 cases metastases caused paraplegia. There were 5 patients with cord bladder and 7 with severe root pains. Acute gastric ulceration was found to exist in 3 cases, but in only 1 case was perforation the cause of death.

Roentgen therapy following operation is believed to be the best method of treatment, and the various dosages are set forth. A group of 15 patients received between 4,000 and 10,000 roentgens with a survival rate of 14 months. Some patients received unusually large quantities the highest being 30,000 roentgens to the skull and spine over a period of 3½ years.

As a result of their studies, the authors have made two important decisions: (1) that temporization with preliminary trials of roentgenotherapy are errors of judgment, for the nature of the lesion can only be presumed on a statistical basis, and a child with a benign lesion may lose his chance for surgical removal during this period; (2) that Torkildsen's procedure is indicated at any time after the primary exploration of the posterior fossa, when the flow of cerebrospinal fluid becomes obstructed.

ADRIEN VAN BRUGGEN, M.D.

Postoperative Period of Survival of Patients with Oligodendroglioma of the Brain: Report of 25 Cases HENRY A. SHERKIN, FRANCIS C. GRANT and JOHN H. DREW *Arch. Neurol. Psychiat. Chik.* 1947 58 70.

The classification of brain tumors rests on a fairly solid foundation: it is based on the histological picture and the history of the patient. From time to time readjustments are necessary in any scheme. A type of glioma known as an oligodendroglioma has long been regarded as being relatively benign and the survival period, even after incomplete removal of the lesion is long—from 3 to 5 years.

The authors' study is based on 25 cases of oligodendroglioma observed at the Hospital of the University of Pennsylvania. In 6 cases the tumors were intraventricular and in 19 cases intrahemispheric. It is pointed out that these tumors infiltrate the brain and consequently it may be impossible to remove them completely. Thirteen tumors were sufficiently calcified to be seen in preoperative roentgenograms. 17 of the 19 intrahemispheric tumors were situated in one or the other or in both of the frontal lobes. The average duration of symptoms was 8 months in the patients with intraventricular tumors and 35 months in those with intrahemispheric tumors. Epileptic seizures occurred in 18 of the 19 patients with intrahemispheric tumors. Seeding of the ependyma adjacent to the intraventricular tumors was noted but there was no dissemination through the cerebrospinal axis.

Five of the 6 patients with intraventricular tumors survived operation, and at the end of 50 months

only one is living the average survival of the whole group was less than 2 years.

The views of other authors on the subject of oligodendrogliomas are discussed.

ADRIEN VER BRUGGHE, M.D.

SPINAL CORD AND ITS COVERINGS

The Occurrence of Extensor Spasm in Patients with Complete Transection of the Spinal Cord.

MAXIM B. MACHOT and ROBERT A. KIRK. *N England J M* 1945, 38:31

From the Paraplegia Service, Cushing Veterans Administration Hospital Framingham, Massachusetts, a preliminary report is given on observations relating to certain patterns of involuntary activity exhibited in 57 verified cases of complete transection of the spinal cord. The duration of complete severance of the cord was 2 or more years and the levels of cord transection ranged from the second to the twelfth dorsal vertebrae.

Earlier investigators have stated that extensor spasm is a sign of an incompletely divided spinal cord. However in these 57 cases of complete division of the cord it was noted that 19 patients exhibited predominant extensor spasms in the muscles innervated below the level of the severance. Two patients showed flexor spasms alone, and 5 showed approximately equal extensor and flexor spasms.

In their experience, the most typical order of events following complete transection of the spinal cord is spinal shock gradual return of reflex activity alternating flexor and extensor spasms and finally predominant extensor spasms. In present day paraplegics, because of the longer duration of the individual's life the stage of predominant extensor spasm is more frequently observed. The authors conclude from their study that extensor spasm in skeletal muscles innervated below the level of the spinal cord transection is not conclusive proof of an incomplete division of the human spinal cord.

JOHN L. BELL, M.D.

Skeletal Traction and Anterior Decompression in the Management of Pott's Paraplegia. NORMAN M. DOTT. *Edinburgh M J* 1947 54:690.

In Pott's disease of the spine, exhibiting paraplegia, skeletal traction and anterior spinal decompression was used in 31 patients from 1944 to 1947. Skeletal traction is advocated as a valuable adjunct in correcting and maintaining fixation of the spine in Pott's disease with or even without paraplegia. The anterior spinal decompression operation is used to expose the internal gibbus, and it is advocated over laminectomy for the relief of spinal cord compression when a sufficient intraspinal abscess is not present.

Skeletal traction is used in combination with recumbent fixation in a plaster shell. For cervical and upper dorsal disease Blackburn tongs are applied to the skull with from 3 to 6 pounds of traction. For middorsal and lower dorsal disease, 20 to 30 pounds of traction is obtained by attaching a strong spring to

the skull tongs and transfixing the tibiae to the foot pieces of the plaster shell by pins. Marked improvement in paraparesis has been noted by the use of this method, without operative procedure, to correct the deformity. Patients are more comfortable, especially in ventral shells.

The anterior spinal decompression operation was used in 18 cases to expose the internal deformity causing the spinal cord compression. In acute, rapidly progressive paraparesis, the author considers the operation as an emergency procedure to combat the danger of acute ischemia of the spinal cord. The operation is indicated also in patients with chronic progressive paraparesis and in those in whom adequate fixation is difficult because of spasms of the paralyzed extremities.

Three deaths occurred among the 18 patients operated upon 2 of these were due to anemia in the immediate postoperative period. One patient received no benefit from the anterior spinal decompression. Two patients developed acute nephritis in the postoperative period with subsequent recovery. Twelve patients had complete spinal cord recovery and 5 had nearly complete recovery. Improvement in the general health was rapid following operation. Bony recovery is attributed to the improvement in general health and not to the operation. Bone grafting in patients who have had recovery of function of the spinal cord is left to the discretion of the orthopedic surgeon and the tuberculous expert.

JOHN L. BELL, M.D.

PERIPHERAL NERVES

Tantalum Foil Cuffs in Peripheral Nerve Surgery. EUGENE E. CLIFFTON. *Surgery* 1945, 3:307

The new metal tantalum was developed just prior to World War II for use especially in peripheral nerve surgery. It was advocated that tissue reactions or adhesion formation would be avoided inasmuch as tantalum was an inert metal.

As time went on it became apparent as more and more nerves were re-explored that ingrowth of scar tissue into the suture line or damaged nerve was not prevented but that dense scar tissue formation occurred both outside and inside of the smooth cuff foil.

Cliffton reports a series of cases, including only those in which sufficient time has passed for adequate follow-up. In 364 neurotomyphies reported, the return of function was not appreciably altered by the use or omission of the tantalum cuff; however the development of paresthesias or trigger points was more prevalent in cases in which foil was used. In 16.8 per cent of 16 cases of neurolyses in which foil was used operation was done again because of the presence of a trigger point, whereas in only 2.5 per cent in which foil was not used reoperation was found necessary.

In a review of the cases in which reoperation was carried out it was certain that the nerves from which foil was removed were more scarred and damaged

and the operative procedure was more difficult than in those in which the nerve was not wrapped in foil. Wherever there were cracks in the foil there was increased scar formation. In 2 cases it was certain that at the first operation damage to the nerve was minimal when the foil was applied whereas at the second operation there was serious scarring and neuroma formation. In other cases the changes ranged from marked edema of the nerve to serious scarring moderate neuroma formation or partial constriction.

Of the cases necessitating reoperation 60 per cent in which foil was used showed improvement after the second operation and all but 2 lost their trigger points whereas only 27 per cent of those in which foil was not initially used showed improvement. This would lead one to believe that the foil in these cases was actually a harmful element.

It must be pointed out that the poor results may have been due to errors in tantalum application such as (1) cracking the foil while preparing or applying it, or (2) constricting of the nerves with sutures tied too tightly in the attempt to hold the foil in place.

If tantalum is to be used infinite care must be used in preparing and applying it. One suggested method in neurorrhaphies is to place a formed cuff over one end of the nerve up onto the trunk and then slip it back over the suture line when the suture is completed. Another method involves preparation of the cuff around a smooth round object and then snapping it in place on the nerve in order to avoid ligatures.

Clifton concludes that tantalum foil as a cuff in peripheral nerve surgery has not proved to be of value in this series of cases its routine use is not advised unless the operation is the first of a two-stage procedure in which case a pseudomembrane surrounding the foil tends to make a smooth gliding surface for the nerve at the suture line. If the time interval between stages is not to be over 2 months.

GEORGE R. GRANT, M.D.

Concerning the Surgical Treatment of Traumatic Injury to the Upper Division of the Brachial Plexus (Erb's Type) ALEXANDER LURJE. *Ann Surg* 1948 127: 317

In injuries of the "upper primary fasciculus" of the brachial plexus (formed by the confluence of C_5 and C_6 roots) the classical treatment of choice has been resection of the neuroma with direct suture when possible. If the defect was too great to permit suture transplants were used but usually with little success. Occasionally it has been possible to employ a neurotizer that is the implantation of the peripheral end of a neighboring nerve into the distal portion of the divided upper primary fasciculus. Sometimes there was considerable difference in the dimensions of the neurotizer and the cut end of the brachial plexus or else the damage may have been so severe that the ordinary neurotizer such as the phrenic, long thoracic nerve or one of the anterior thoracic nerves could not be used.

The authors concluded that certain muscular branches of the plexus might be used as neurotizers without marked functional impairment of the extremities. This enables suture to be carried out distally from the site of trauma. The advantages and disadvantages of various nerves as neurotizers are described. The authors discuss in detail the careful observations that must be made as to the adequacy and choice of neurotizers. Clinical and electrophysiological studies of the degenerated recipient nerves must be made preoperatively. During operation stimulation with the inductorium and determination of chronicity should likewise be carried out. A nerve donor which has only a part of its fibers degenerated may show fair function in electrical testing. The degenerated recipient nerve is considerably smaller than the usual normal one therefore considerably thinner donor nerves can be sutured end-to-end to thicker recipients even if the ratio of cross section is 1 to 2 or 1 to 3.

The authors present a case of Erb's palsy in which neurotization was performed. Eight months prior to operation the patient had suffered a shrapnel wound of the left side of the neck. There was marked atrophy of the scapular deltoid and biceps muscles with complete loss of function in the shoulder joint except for adduction by contraction of the pectoralis and the latissimus dorsi. There was complete absence of flexion in the elbow with adequate extension absence of supination and absence of adequate pronation. Movements in the radiocarpal joint, wrists and fingers were preserved. There was anesthesia in the C_5 and C_6 dermatomes. At operation the long thoracic nerve was stimulated and contraction of the serratus muscle occurred. A portion of the nerve was divided, the branches being left to the uppermost digitations of the serratus. The proximal portion was then inserted into the suprascapular nerve which had been divided below the clavicle. Two branches of the anterior thoracic nerve were identified they responded to stimulation and these were sutured to the distal end of the musculocutaneous nerve. Three ramus of the triceps were dissected out two of these were divided and turned upward to be implanted into the axillary nerve. In all anastomoses the callipers of the donor and recipient nerves were nearly equal.

Fourteen months after operation there was disappearance of atrophy of the scapular deltoid and biceps muscles. Contraction of the deltoid abducted the shoulder 35° with the patient in the supine position the deltoid could maintain the extremity in a vertical position. Flexion at the elbow was complete with use of the biceps although strength was less than that of the normal side. Contraction of the biceps had synchronous contractions with the pectoralis and when the deltoid contracted the triceps muscle likewise showed a synchronous response.

The authors regard the result as being fairly satisfactory and they advocate the procedure for similar cases.

RICHARD C. SCHWEIDER, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Benign Lesions of the Breast HARRY A. OBERHELMAN *Surg. Clin. V America* 1948, 28 95

The author studied 556 consecutive breast lesions and found 2 per cent to be inflammatory, 40 per cent malignant and 58 per cent benign. Of the 318 benign lesions, 202 were true tumors and 316 were of the chronic cystic mastitis variety. Only 15 benign true epithelial and 16 benign true connective tissue type tumors were found. The greatest number (71) were lesions of both epithelial and connective tissue type (fibroadenomas, 69 and cystosarcoma phyllodes, 4). The author divided the 216 cases of chronic cystic mastitis into proliferative (182) and nonproliferative (84) types.

All of the benign tumors should be removed surgically. The author recommends the Warren incision in the thoraco-mammary groove. This incision offers the advantage of direct inspection and palpation of the breast and leaves a concealed scar. For intraductal papillomas a semicircular incision at the periphery of the areola is advisable.

A discussion is given of the various anatomic alterations that the female breast normally passes through as a result of the action of the various sex hormones present during the life cycle of the individual. It is now generally accepted that the various types of anatomic lesions in chronic cystic mastitis are the result of prolonged or repeated periods of endocrine imbalance due probably to ovarian dysfunction.

There has been much confusion in the literature in the nomenclature for chronic cystic mastitis. Also there is a uniform lack of agreement as to whether the different types of chronic cystic mastitis lesions represent different stages of the same disease or whether they are separate disease entities.

Cole and Rossiter classify chronic cystic mastitis into 4 types: (1) the adenofibrosis type—a proliferation of fibrous tissue containing scattered groups of acini, (2) the benign parenchymatous hyperplasia—consisting of proliferation of the epithelial structures of the glands and ducts, (3) the precancerous hyperplasia representing a high grade of atypical epithelial hyperplasia with mitosis and (4) cystic disease—localized cysts formed largely during the process of involution.

The author groups 1 and 4 together as the non-proliferative and groups 2 and 3 together as the proliferative types. Aspiration transillumination and palpation will usually enable one to make the correct diagnosis. If there is any question biopsy should be resorted to.

The treatment of chronic cystic mastitis may be conservative or surgical. Attempts to restore the disturbed endocrine balance by administering hormones have been unsuccessful. The author after

watching the patients' condition through at least one menstrual cycle feels that grossly palpable breast lesions in chronic cystic mastitis should be widely removed. If malignant or if the pathologist is suspicious of malignancy the surgeon should carry out a radical mastectomy.

The author cites some of the views in the literature on the subject of whether or not chronic cystic mastitis is a precancerous lesion. Numerous views in support of each side are given. The author believes, after weighing all the evidence at hand, that in a limited number of instances in the highly proliferative forms such as the adenopapilloma the lesion may for all practical purposes be considered a precancerous one and should be treated as such by radical mastectomy. ROBERT R. BIGELOW M.D.

Gynecomastia Due to Infectious Hepatitis of the Homologous Serum Type GERALD KLATSKIN and EMANUEL M. RAFFAPORT *Am. J. Med. Sc.* 1947, 214 121

The authors report 2 cases of bilateral gynecomastia occurring during convalescence from infectious hepatitis. The hepatitis was of the homologous serum type and ran a severe and prolonged course but there was no evidence to suggest the development of cirrhosis. The gynecomastia subsided spontaneously so that early recognition of the relationship between breast lesions and hepatitis precluded needless surgery. Hormone excretion studies in infectious hepatitis suggest that hyperestrinemia is an important factor in the pathogenesis of this type of gynecomastia.

The normal liver inactivates estrogen, but in experimental liver injury and in clinical cirrhosis this function is seriously impaired. The gynecomastia that occurs in cirrhosis is thought to be due to the resultant hyperestrinemia, but other factors may be contributory. Certainly atrophy of the testes and chronic malnutrition which are common complications of cirrhosis may play a role since both may give rise to gynecomastia in noncirrhotics.

Gynecomastia has not been reported as a complication of infectious hepatitis. Both of the authors' patients suffered unusually severe and protracted jaundice and showed low serum protein levels before the onset of hepatitis. Evidently the factors responsible for sufficient growth of the breast to produce gynecomastia must be operative over a long period or must come into play only after unusually severe liver damage. EDWIN W. PASSARELLI M.D.

Discussion: The Treatment of Cancer of the Breast SIR GORDON GORDON TAYLOR, R. McWHITER, SIR STANFORD CARR, R. S. HANDLEY and F. M. ALLCHIN *Proc. R. Soc. Med., Lond.* 1948, 41 118.

GORDON TAYLOR states: I am a simple soul, a simple surgeon profoundly ignorant of the recondite

TABLE VIII.—SURVIVAL RATE OF ALL IN OPERABLE CASES IN THE PERIOD 1935-1940 MAIN METHOD OF TREATMENT—RADICAL SURGERY AND POSTOPERATIVE RADIOTHERAPY TOTAL CASES 221

Years after treatment	Number of cancer deaths	Number exposed to risk	Chance of dying in any one year	Survival rate, per cent
	138		6.24	7.8
	54	8	6.51	13
3	13	99	4.38	7
4		53	3.8	
5		6	167	

In the period from 1941 to 1945 there were 945 "operable" cases and the main method of treatment was simple mastectomy and postoperative radiotherapy. The 5 year survival rate was 55.9 per cent.

It will be noted that the 5 year survival rate for the period from 1935 to 1945 was higher than that for the two preceding periods. Statistical examination shows that the differences are significant. The findings therefore suggest that by not dissecting the axilla the risk of dissemination of cells to distant sites is reduced.

In the period from 1930 to 1934 few inoperable cases were recorded and no patients survived to the fifth year.

In the period from 1935 to 1940 the number of inoperable cases referred was 221 and at the end of 5 years only 2.5 per cent of the patients were alive. The results are little different from those obtained during the period from 1930 to 1934 and suggest that when radical removal was attempted the postoperative radiotherapy was rendered ineffective by dissemination of cells at the time of operation.

In the period from 1941 to 1945 the number of inoperable cases was 404 and the 5 year survival rate was 14.1 per cent.

Again the survival rates are higher than any obtained before and the differences are statistically

TABLE IX.—SURVIVAL RATE OF ALL INOPERABLE CASES IN THE PERIOD 1941-1945 MAIN METHOD OF TREATMENT—SIMPLE MASTECTOMY AND POSTOPERATIVE RADIOTHERAPY TOTAL CASES 404.

Years after treatment	Number of cancer deaths	Number exposed to risk	Chance of dying in any one year	Survival rate, per cent
	136	201	260	54
	23	2	4.56	99.4
3	5	69.5	260	13.8
		26	24	5

TABLE X.—SURVIVAL RATE OF ALL OPERABLE AND "INOPERABLE" CASES IN THE PERIOD 1935-1940. MAIN METHOD OF TREATMENT—RADICAL SURGERY AND POSTOPERATIVE RADIOTHERAPY TOTAL CASES 790.

Years after treatment	Number of cancer deaths	Number exposed to risk	Chance of dying in any one year	Survival rate, per cent
	3	766.5	264	70.6
	56	555.5	124	70.3
3	63	305	163	41
		52	58	33.7
		267	203	51

significant when comparison is made with either of the two preceding periods.

In the period from 1941 to 1945 the total number of cases operable and "inoperable" referred to the Royal Infirmary was 1,345 and the 5 year survival rate of 43.1 per cent is higher than that of the period from 1935 to 1940. Statistical examination shows that the difference is significant.

Carcinomatous breast without distant metastases. When the cases with clinical or roentgenographic evidence of distant metastases are excluded from the total patients seen in the period from 1941 to 1945 the 5 year survival rate is 50.1 per cent.

PRESENT TREATMENT METHODS

The technique of simple mastectomy and postoperative radiotherapy is being continued with the addition of ovarian irradiation, which has been added with a view to influencing distant metastases.

Technique of simple mastectomy and postoperative radiotherapy. This method is a combination of two procedures which must be co-ordinated if the best result is to be obtained.

The following points are of importance:
1. Preoperative preparation by iodine is contra-indicated because it lowers the skin tolerance to radiotherapy.

TABLE XI.—SURVIVAL RATE OF ALL "OPERABLE" AND "INOPERABLE" CASES REFERRED IN THE PERIOD 1941-1945 MAIN METHOD OF TREATMENT—SIMPLE MASTECTOMY AND POSTOPERATIVE RADIOTHERAPY TOTAL CASES, 1,345

Years after treatment	Number of cancer deaths	Number exposed to risk	Chance of dying in any one year	Survival rate, per cent
	26	1,345	94	80.6
	59	830.5	15	65.5

Years after treatment	Number of cancer deaths	Number at risk	Chance of dying in any one year	Survival rate, per cent
	130	1,46		89.9
1	119	134.5	.15	74.5
2	75	130.5	.22	62.
3	23	110.5	.13	54.8
5	8	64	.085	50

2 The skin incision and the undermining of the skin flaps should be as limited as possible so that tissue spaces outside the area to be irradiated will not be contaminated with malignant cells liberated during the operation

3 Excessive skin should not be removed for tension on the skin flaps may be associated with failure of the wound to heal and delay in the application of radiotherapy. Tightly stretched skin flaps do not tolerate radiation well. Skin grafting does not overcome the difficulty for grafts do not tolerate roentgen ray treatment well.

4 When the primary tumor is mobile on the pectoral fascia, the fascia should not be removed as this promotes fibrosis of the pectoral muscle. If the tumor is firmly fixed to the pectoralis major the muscle should be removed together with the breast.

5 If there are no palpable axillary glands no dissection should be performed, but superficial mobile glands in the subpectoral region and outside of the axilla may be removed. Any further dissection of the axilla will defeat the whole purpose of the treatment method advocated.

6 If the patient is very stout it is better to carry out a radical operation because in stout patients it is difficult to deliver an adequate dose of roentgen rays to the axilla.

7 Supraclavicular glands should never be removed because these glands are easily and effectively dealt with by radiotherapy.

8 Adhesive should not be applied to the skin after the operation because this lowers the tolerance of the skin to radiation.

The following points are of importance in the post operative treatment by radiotherapy.

1 Only one full course of x ray treatment should be given. The practice of repeated courses at intervals of from 3 to 6 months has no place in the treatment of any form of malignant disease in which cure is to be attempted and is just as illogical as partial removal of a tumor at intervals of 3 to 6 months.

2 X ray treatment should be commenced as soon as possible after the operation the usual interval is 2 weeks.

3 The chest wall must be treated by tangential or glancing fields so as to avoid lung fibrosis.

4 An adequate dosage must be given and in Edinburgh the patients receive a minimal tumor dose of 3750 roentgens in a period of 3 weeks.

5 The x ray apparatus must be sufficiently powerful to deliver an adequate depth dose in the axilla and it is doubtful if effective radiotherapy can be given with an apparatus of lower voltage than 250 kv.

CAGE suggests the following classification of cancer of the breast: stage 1—tumor of the breast only; stage 2—tumor of the breast with skin changes or involvement of the axillary glands or with both; stage 3—tumors of the breast with involvement of the supraclavicular glands or contralateral axillary glands, or fixation to the pectoral fascia; and stage 4—skeletal or visceral metastasis.

The choice of the method of treatment should be guided by many factors. The best results following the best form of treatment are not unnaturally achieved in the best cases and so far radical mastectomy achieves them more frequently than all other therapeutic measures.

Radiation is of value.

1 As the sole method of treatment in stage 3 cases the end results following radiation are better than those following surgery.

2 As a preoperative measure in stage 2 cases in which improved results can confidently be expected.

3 As a postoperative measure chiefly in stage 2 cases.

HANDLEY said that he had removed the second intercostal space gland of the internal mammary lymphatic chain in 20 cases of carcinoma of the breast, and his collaborator Thackray had examined the material microscopically. The study had so far been chiefly a pathological one with the object of finding out how often the internal mammary glands were invaded in carcinoma of the breast and the second intercostal space had been chosen because it contained the largest and most constant gland of the chain. In the 20 cases examined no glandular involvement had been found in 6 patients; both intercostal and axillary glands were invaded in 9 patients; in 3 patients only the axilla was involved and in 2 only the intercostal gland. It was easy to open the intercostal space but more difficult to find the gland, although matting of the tissues around the internal mammary artery usually betrayed invasion of the space. The largest invaded gland encountered had been the size of an orange pip; the smallest the size of a pinhead. Although clinical recurrence in the second intercostal space was not very common in these days it was difficult to believe that carcinoma cells lying almost on the pleura were harmless. If the intercostal glands were invaded the patient could not be cured by surgery alone and additional radiotherapy was necessary. It was thought that if the axilla was clinically free from invasion or showed mobile glands, the operation should start with a second intercostal space biopsy. If a rapid

frozen section showed the space to be free from growth, a radical mastectomy should be done. If however the space was invaded the operation should be limited to a simple mastectomy with additional removal only of such of the axillary contents as are within easy reach. Radiotherapy must deal with the deposits within the chest and might as well cope with the apex of the axilla.

ALLCHIN emphasized the value as a preoperative measure of irradiation of tumors of the breast in stage 3 cases. Those who have been fortunate enough to see the results of such treatment could not but fail to be impressed. The gross changes produced by interstitial radium treatment so ably carried out by Keynes and a few others had been repeated with x-rays. Many breasts thus irradiated had shown a complete absence of active cancer cells on histological examination after removal. These were what might be termed the more radiosensitive tumors. In the more resistant types, shrinkage of tumors is not so marked and many malignant cells are found throughout the breast after irradiation. The fact must be recognized that in both types there are still potentially malignant cells remaining which may start into a period of activity at some future date, hence the necessity for the operative procedure after irradiation before such activity begins. These remarks applied with even greater emphasis to the axillary glands which in Allchin's technique are irradiated at the same time as the breast. As it was more difficult to remove all traces of malignant cells from metastatic glands, the necessity for the clearance of the axilla became even more apparent.

JOHN J. MALONEY M.D.

Management of Advanced Cancer of the Breast. ARTHUR W. ECKSTEIN. *Radiology* 94B, 50: 7

Advanced cancers of the breast may be divided into two groups (1) those in which the disease is local but has advanced to ulceration and fixation to the chest wall and (2) those with widely disseminated metastases. The former is best managed by surgery supplemented with roentgen therapy as indicated.

The patients with advanced metastases are best treated symptomatically. Castration, either surgical or with x-rays, is believed to be the most important single procedure to retard the course of advanced breast cancer. Pain due to nerve or bone involvement may be controlled with x-rays, surgical means, cobra venom, or narcotics. Questions asked by persons in full possession of their faculties should be truthfully answered, either or infirm patients may be spared needless worry by indirect replies.

TRACHEA, LUNGS, AND PLEURA

Pulmonary Cavernous Hemangiomas with Arteriovenous Fistula: Surgical Management. J. DEWITT BIGGARD. *Ann. Surg.* 1947 26, 905.

Visceral hemangiomas are uncommon. Autopsy records indicate an incidence of less than 0.3 per cent.

Hemangiomas of the lung are rare and for this reason this case is added to the small group previously reported.

How these lesions should be classified is of academic interest principally. Anatomically they are hemangiomas, physiologically arteriovenous fistula. Probably all pulmonary hemangiomas are congenital. Their presence has been demonstrated in newborn infants, and in some of the reported cases there has been a history of cyanosis since infancy. Way symptoms do not appear until later in life in some cases may be explained by the fact that cyanosis and symptoms associated with it result from a large shunt of blood from the pulmonary artery to the pulmonary veins. It has been estimated that at least 25 per cent of the blood must be shunted before cyanosis is apparent. It would seem reasonable to assume that a small fistula through a hemangioma would progressively enlarge to a size that would produce symptoms as time passed. There is no record of a pulmonary arteriovenous fistula of traumatic origin and, furthermore, in the reported cases there is no definite evidence of an etiologic factor other than a congenital one.

In terms of oxygen saturation the direction of blood flow through a fistula in the lung is the reverse of that through a shunt in the systemic circulation. Therefore much of the blood leaving the left ventricle is venous and unsaturated with oxygen so that some degree of cyanosis is a constant symptom. The cyanosis is somewhat distinctive in that there is no associated enlargement of the heart or other evidence of a cardiac lesion but there are, with exceptions, compensatory polycythemia, polyemia, and hyperhemoglobinemia with an increased hematocrit and reduced oxygen saturation. The degree of cyanosis and polycythemia is dependent upon the size of the fistula and the volume of the shunt, and the increase in the number of red cells accounts for the increased blood volume there being no appreciable increase in serum and none in the number of white blood cells and platelets. The blood picture differs also from that of true polycythemia by absence of changes, such as basophilic stippling and immaturity of the white cells. A constant finding is the presence of one or more chronic nonprogressive pulmonary lesions which roentgenographically are cylindrical masses and which under the fluoroscope, often may be observed to pulsate. In laminagraphs the cylindrical configuration and branching character of the lesions may be demonstrated.

In five of the reported cases and in the author's case a continuous murmur was heard over the pulmonary lesions and in each instance it was loudest at the end of deep inspiration.

Clubbing of the fingers and toes is a constant finding. The extent of these changes varies with the duration and the degree of cyanosis.

Other symptoms are variable, including pain in the chest, cough, dyspnea, asthmatic paroxysms, hemoptysis, fatigue, vertigo, faintness, headaches, syncope, and disturbances of speech and vision.

Treatment consists of ablation of the fistula. This can be accomplished only by surgical interference. Operation is indicated in the absence of incapacity and even in the absence of noteworthy symptoms because of the risk of fatal hemorrhage from rupture of the hemangioma and of sequelae resulting from thromboses secondary to the polycythemia.

Seven patients, including the author's, have been operated upon and all have been cured. In 4 cases (Shenstone and Jones, Jones *et al.*, Adams *et al.* and Goldman) a total pneumonectomy was done in 3 including the author's case, a lobectomy and in 1 case (1 of Jones) local excision of multiple bilateral lesions was done. The ideal operation would eradicate the hemangioma by interrupting the vessels communicating with it without sacrificing pulmonary tissue. Unfortunately this was technically impossible except in Jones' case.

Cavernous hemangioma of the lung is a relatively rare lesion but not as rare as the number of reported cases suggests. It is probably a congenital lesion and may exist without symptoms until an arteriovenous shunt becomes established or enlarges to such a size as to cause considerable reduction in the oxygen saturation of the arterial blood. There is then a characteristic syndrome—a demonstrable pulmonary lesion which may be demonstrated to have characteristics of a vascular tumor by roentgenographic studies and no associated generalized cyanosis with clubbing of the fingers and toes. In most cases, there is a compensatory polycythemia.

Treatment consists of ablation of the fascicular fistula. Ideally this should be accomplished without sacrificing pulmonary tissue, as was done in 1 case. Usually this is technically impossible and eradication can be accomplished only by means of a lobectomy or pneumonectomy. Since there is much hazard of a fatal hemorrhage or of thrombotic sequelae from an associated polycythemia, surgical interference is indicated in the absence of incapacity and even in the absence of troublesome symptoms if there are no additional factors to increase the risk seriously. JOHN E. KIRKPATRICK, M.D.

The Glandular Bronchial Epithelium as, Bronchial Adenomas (Les epithéliomas glandulaires bronchiques: a structure remanente et a évolution prolongée)
M. BARIATY and J. PAILLAS. *J fr méd chir thorac* 1947 1 356

Bronchial adenomas are characterized by slow growth, rare metastases, and by their polypoid nature as seen through the bronchoscope. They are usually composed of an intrabronchial as well as an extrabronchial portion joined together by a narrow pedicle extending through the annular cartilaginous rings. A fibrous capsule tends to form around that portion extending into the pulmonary parenchyma. The intrabronchial portion most often causes complete obstruction of the bronchus from which it arises so that atelectasis, bronchiectasis, or suppuration of the lung distal to the lesion are commonly encountered.

The exact place of the adenomas with respect to benignity or malignancy is debatable. The slow growth and absence of atypical cells are in favor of their benign nature. The slow but progressive extension and the occasional distant deposits suggest that some of them at least are malignant.

Surgical extirpation either by lobectomy or pneumonectomy is strongly advised for with complete removal the best results of treatment of all pulmonary neoplasms can be expected. Removal through the bronchoscope is to be condemned except in rare instances. Such a procedure which removes only the endobronchial portion of the tumor provides only momentary relief because the large extrabronchial portion assures persistence of the tumor. The purely endobronchial type of lesion is observed but rarely. ORVILLE F. GRIMES, M.D.

Carcinoma of the Lung ADRIAN LAMBERT *Am J M Sc* 1948 215 1

The importance of early diagnosis in lung cancer is emphasized by the fact that in 80 per cent of the 349 cases studied on the Chest Division of Bellevue Hospital, New York, over a 7 year period (1939-1946) the diagnosis was not made when the cancer was sufficiently localized to permit exploration. Only 70 patients or 20 per cent were explored.

Among the 70 patients explorable, resection was possible in only 25 or 7.2 per cent of the total group.

The duration of symptoms before hospitalization for the resectable group averaged 7 months and 7 days; for the nonresectable group, 9 months and 10 days.

The average hospital time until exploration was 40 days and the total hospital time averaged 87 days. Pneumonectomy was done in 20 of the 25 cases and lobectomy in 5.

Sixty-three of the patients were examined by means of the bronchoscope. Thirty-six (57.1%) had a positive biopsy in 11 (17.5%) the biopsy was inconclusive and in 16 (25.4%) the bronchoscopy findings were negative. The daily sputum volume could not be correlated with the resectability.

Seventeen of the 70 patients operated upon died in the hospital, a mortality of 24.3 per cent. Five year survival has been attained by only 1 patient thus far. FRANK B. QUEEN, M.D.

ESOPHAGUS AND MEDIASTINUM

Resection of the Esophagus for Persistent Stricture.
CHARLES B. PUESTOW and STEPHEN J. CHESSE.
Arch. Surg. 1948 56 34.

Puestow and Chess believe that resection of the esophagus for stricture with esophago-gastric anastomosis high in the chest is becoming practicable largely as the result of progress in anesthesiology and in the use of antibiotics and also as the result of experience gained in the use of this procedure in the treatment of carcinoma of the esophagus. However, radical resection is still a dangerous procedure and may carry with it a higher mortality than more

frozen section showed the space to be free from growth a radical mastectomy should be done. If however the space was invaded the operation should be limited to a simple mastectomy with additional removal only of such of the axillary contents as are within easy reach. Radiotherapy must deal with the deposits within the chest and might as well cope with the apex of the axilla.

ALLICHIU emphasized the value as a preoperative measure of irradiation of tumors of the breast in stage 3 cases. Those who have been fortunate enough to see the results of such treatment could not but fail to be impressed. FRANK B. QUEEN, M.D.

ESOPHAGUS AND MEDIASTINUM

Resection of the Esophagus for Persistent Stricture.
CHARLES B. PUESTOW and STEPHEN J. CHESSE
Arch. Surg. 1948 56: 34

Puestow and Chess believe that resection of the esophagus for stricture with esophagogastric anastomosis high in the chest is becoming practicable, largely as the result of progress in anesthesiology and in the use of antibiotics and also as the result of experience gained in the use of this procedure in the treatment of carcinoma of the esophagus. However, radical resection is still a dangerous procedure and may carry with it a higher mortality than more

conservative methods of therapy. Nevertheless the end-result makes it justifiable as it restores the patient a normal eating habits and frequently overcomes pre-existing abnormal psychic states.

Four case histories of patients in whom persistent stricture was treated by resection and anastomosis are reported in detail. Three survived the operation and are doing well the fourth patient died on the sixth postoperative day with atelectasis of the left lung and hydrohemothorax, edema of the right lung, and bronchopneumonia. There was, however no evidence of leakage from the gastrointestinal tract.

A modified Sweet technique of esophagectomy and gastroesophageal anastomosis was used in each instance. Removal of the seventh rib division of the sixth and fifth ribs, and insertion of the Rawson Abbott tube through the anastomosis are the main departures from Sweet's procedure.

Certain anatomic relationships which may protect against pitfalls the use of the procedure are discussed as well as the preoperative and postoperative care of the patient, complications and the treatment.

STEPHEN A. ZICKMAN, M.D.

Surgical Treatment of Perforation of the Esophagus. JOHN M. DORSEY *Arch Surg* 94:5, 56-57.

To the list of spontaneous perforations of the esophagus must now be added that which may follow instrumentation. This inevitably will occur as peroral endoscopy for diagnosis becomes more widely used. When positive evidence has accumulated such as subcostal epigastric or shoulder pain, elevation of temperature and leucocyte count followed by persistent pain worsened by deep inspiration in a patient who demonstrated normal findings before instrumentation, then active treatment should be instituted. It should be adequate to the pathologic changes that occur subsequent to esophageal perforation. Four case histories are given to show what was considered adequate therapy.

In the first case treatment with hot compresses and penicillin therapy were sufficient.

In the second case cervical mediastinotomy and drainage with penicillin resulted in recovery.

The third case was that of a patient who had swallowed a piece of beef which lodged above the esophageal hiatus of the diaphragm. It was removed partly through a gastrotomy and partly by means of esophagoscopy.

Dorsey discusses the use of papain as a digestant in these cases, particularly where there is no evidence of perforation. The papain will digest the bolus and substitute for the need of surgical intervention.

The fourth case was that of a patient who had swallowed a piece of lamb chop and sustained a perforation following esophagoscopy. Diagnosis was made because of the widening of the mediastinal shadow on roentgenogram, and the rise in temperature. A gastrotomy and mediastinotomy resulted in complete cure of the patient.

STEPHEN A. ZICKMAN, M.D.

Carcinoma of the Esophagus. An Analysis of 145 Cases, with Special Reference to Metastases and Extensions. GEORGE J. TAQUINO and GERALD F. JOSEPH. *Ann Otol Rhinol* 54:7 56-61.

In 1935 in a report on 506 patients with carcinoma of the esophagus observed at Memorial Hospital in New York over the 13 year period ending in 1931, Watson made the statement that a cured case of this disease is a medical curiosity and that it seems wise in view of its rapidly fatal character to attempt cure only in the very few favorable cases and to treat the remainder routinely by palliative methods. In 1942, in a review of 930 cases of carcinoma of the esophagus this same observer stated that after 15 years' experience with the disease he had become considerably more optimistic about it. The reason for his optimism was twofold: the method of external radiation carried out for the previous 2 years at Memorial Hospital and the recent advances in trans thoracic esophagogastronomy and esophagogastricomy. In 1945 Sweet put on record 73 radical resections followed by some form of anastomosis for carcinoma of the esophagus. The most significant feature of his report was that, while only one of these operations had been performed in 1939, 34 had been performed in the first 10 months of 1944. Since that time Sweet has materially increased the number of his own cases, and numerous other surgeons have put on record many other cases in which curative operations were performed.

These observations indicate that the professional pessimism with which carcinoma of the esophagus was once viewed has over the past decade become a modified and cautious optimism. Cured patients perhaps are no longer rare but they remain exceedingly uncommon. Radical resections, however are no longer surgical curiosities. In fact they have become standard procedure in every case that is not frankly hopeless for two very good reasons, namely the remarkable recent advances in intrathoracic surgery and the completely justifiable position that if a disease is hopeless without treatment almost any risk that offers a chance of salvage is worth the taking.

The general situation of course is not nearly as bright as these facts might suggest. The outlook on carcinoma of the esophagus has changed, it is true. Technical advances in both surgery and radiation therapy have made cures of the disease at least theoretically possible. Surgical courage allied with surgical judgment, has extended the indications for resection while at the same time the mortality, although still not small, is no longer prohibitive. However to the great majority of patients with carcinoma of the esophagus these brilliant advances mean nothing. The disease in most cases is still detected too late to permit any but palliative treatment if indeed to permit any treatment at all.

A study of 45 cases of carcinoma of the esophagus has proved by postmortem examination and the remainder indubitable instances of the disease shows the usual gloomy picture of advanced processes,

widespread metastases and extensions nonresectability and the almost 100 per cent mortality characteristic of most reported series. Two patients who had radical operations were alive when last seen at the end of a year but have been lost from sight. Six patients who had radiation therapy by a new technique have been kept alive from 9 to 18 months. All the other patients in the series are either dead or have no hope of survival because they were not submitted to any procedure which gave them any chance of life.

The duration of symptoms in this series ranged from less than a month to 18 months (in a single, possibly questionable case). The average duration was less than 5.5 months. Yet metastases were identified by clinical methods in 16 different sites in 38 patients who survived the period of observation and they were identified at autopsy in 19 different sites in 30 of 44 patients subjected to autopsy. In addition, extension of the malignant process was identified in 12 different sites in 20 patients, 17 of whom presented complications in the sites to which exten-

sion had occurred. A total of 88 patients, 60.7 per cent of the whole series, was thus eliminated from all hope of cure by surgery because in this disease radical surgery is contraindicated for all practical purposes when metastases and extensions have occurred. It seems doubtful that radiation therapy, even by new methods, can achieve anything at all in such cases.

The solution of the problem of carcinoma of the esophagus in the general run of cases still seems very far off. Advances in surgery and in radiation therapy are applicable only to the small and highly favored group of patients whose disease is recognized early enough for these measures to be useful. Hope for the rest lies in the recognition by physicians in general that even the most trivial symptoms which might point to the disease must be fully and repeatedly investigated. Since esophagoscopy and biopsy are the definite diagnostic methods, the responsibility of the esophagoscopist for the end results in this disease is correspondingly heavy.

JOHN E. KIRKPATRICK, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Hernia of the Intersigmoid Foramen; A Contribution to the Study of Internal Hernias (Hérnia da fosseta intersigmoide; contribuição ao estudo das hérnias internas) MATEIRO ROCHA and JOSE DODWORTH MARTINS. *Rev. med.* 1917 15 30.

Hernia of the intersigmoid foramen is the most uncommon of the internal hernias, its incidence amounting to 1 per cent. Clinically its symptoms may be limited to some vague pains in the hypogastrium and the periumbilical region but its history reveals repeated attacks of indigestion with epigastric pain and more or less rebellious constipation, which suggests varying degrees of intestinal obstruction. Incarceration of the intestinal loop sometimes occurs suddenly and severely aggravates the condition. This loop always belongs to the ileoterminal group and the clinical picture does not differ essentially from that of the classical mechanical ileus occurring in the small intestine.

Retention of feces and gas is usually early and vomiting also occurs early as a reaction to the initial pain. After the initial period, vomiting may be delayed because of the relatively low seat of the ileus. The pain, of colicky type in the beginning, gradually increases in severity it occurs early with remissions but soon dominates the picture and becomes lancinating. It is located at the level of the inferior mesenteric plexus.

Inspection may show intense peristaltic movements and asymmetry of the abdomen with rounded tumefaction, periumbilical swelling on the right side and hypogastric concavity. This is due to the presence of a more or less voluminous hernial mass in the mesogastrium. The mass is soft, globular somewhat mobile, of variable size and uninfluenced by respiration. Percussion reveals a resonant tympanic sound auscultation discloses gurgling and intestinal sounds. Inspection shows intestinal loops with their peristaltic movements raising the center of the mass when the abdominal wall is thin. As the period of strangulation increases, the distention becomes greater and masks this sign. Circulatory changes resulting in extravasation of blood into the peritoneal cavity cause the appearance of a picture of peritoneal irritation.

The anatomopathologic changes in the sigmoid range from simple subocclusion by compression to torsion or volvulus. They develop slowly and insidiously, and the paradoxical association of ileus of the small intestine with signs of low obstruction is highly suggestive of hernia of the intersigmoid foramen. Roentgen examination often suggests the diagnosis. In complicated hernias, especially in the beginning, roentgenography reveals two suggestive elements: elective distention of some loops, well localized, with regular limits and sacular aspect, and apparent ab-

sence of loops from the left side of the abdomen and the pelvis. With these elements supported by the clinical data it is quite possible to establish a correct preoperative diagnosis.

Treatment is always surgical. Reduction and freeing of the sac are not always easy. The presence of large vessels (sigmoid artery) contraindicates liberating incision. The loops must be freed by cautious traction under careful inspection. Partial incision of the sac and obliteration of the cavity by suture after reduction of the hernial contents, is especially useful in cases of volvulus or incarceration. The anatomic character of the region makes difficult this surgical maneuver which is recommended only in case manual liberation is absolutely impossible. The treatment of the herniated loop is the routine one.

The literature shows a steady decrease in the number of patients who died because they were not operated upon and a gradual decrease in the operative mortality because of early intervention. The authors describe a fatal case in which extensive resection of the small intestine was necessary but impossible.

RICARDO KERN, M.D.

Indirect Inguinal Hernia; A Contrast between the Sites of Recurrence after the Simple and after the Plastic Operation. C. CRAIG, *Annals of the New York Acad. of Med. Sci.* 1917 17 207.

Two series of cases of indirect inguinal hernia in patients operated on by the method of Russell are reported. The second of the series consisted of 54 cases which were carefully followed up. The recurrence rate in the second series was 3.3 per cent.

An analysis of the 20 recurring hernias in both series showed that 19 were indirect in type. In those reoperated on it was found that the new sac reproduced the original one exactly as far as site was concerned. The one direct recurrence was of the Ogilvie tubular type. After plastic operations involving gross interference with the muscles surrounding the inguinal canal there are not only indirect recurrences but also direct recurrences. These direct recurrences are very likely due to the operative interference with the posterior wall of the canal.

It is suggested that the plastic operation should be abandoned, except for certain types of advanced hernia, and that a new operation be devised. This should have as its main principle the establishment of a strong sheet of fascia between the exposed transversalis fascia and the origin of the cord. The author believes that part of the procedure would be reeducation of the muscles.

Two additional methods are described: they are to be used either alone or as adjuncts to other methods: (1) the injection of sclerosing solutions during operation and (2) inversion of the sac. The treatment of 10 large sliding hernias is described as well as that of ordinary cases.

SAMUEL KERN, M.D.

GASTROINTESTINAL TRACT

The Effect of Tetraethylammonium on the Small Bowel of Man WILLIAM P. CHAPMAN JOHN B. STAMBOURY and CHESTER M. JONES. *J. Clin. Invest.* 1948, 27, 34

The present report concerns the effect of tetraethylammonium ion on the intestinal tract of 8 patients as observed by the multiple balloon technique. Three patients were hypertensive of these one patient had a duodenal ulcer and another had had a lumbar sympathectomy 4 years previously without any striking change in blood pressure. Three patients had intractable abdominal pain, presumably intestinal in origin. One patient had gastritis and one had rheumatoid arthritis.

It was found that tetraethylammonium causes an immediate cessation, or marked decrease of motility of the upper small bowel. This effect is more prolonged than the fall in blood pressure or rise in pulse which the drug induces. It is possible that buffer reflexes for the circulation are more highly developed and act for the more rapid return of blood pressure to normal. Within the limitations of the method used, the effect of the drug on the intestine is identical to that of atropine.

It is suggested that the mechanism of action of tetraethylammonium on the small intestine is not solely that of an autonomic blocking agent. Perhaps the drug has an additional action on the intrinsic neuronal structure or on the smooth muscle itself which is responsible for the continued activity following surgical denervation.

The fact that the thresholds for intestinal pain elicited by barium distention were unchanged following the administration of tetraethylammonium suggests that this drug has no significant action on the sensory innervation of the intestine. Its pain-relieving effect must therefore depend on antispasmodic action.

The authors suggest that if continued use demonstrates its reasonable safety, tetraethylammonium may have diagnostic value in implicating smooth muscle spasm as responsible for the features of certain cases of obscure abdominal pain. Its value as a releasing agent in such conditions as ulcerative colitis and intractable peptic ulcer is limited at least at present, by its brief duration of action.

HAROLD LAUFMAN M.D.

Rationale of Therapy in Pruritus Ani. RACHELLE SELTZ. *Am. J. Surg.*, 1948 75, 373

Pruritus ani is a complex syndrome characterized by recurrent attacks of itching, anospasm, insomnia, nervous depression and sluggish peripheral circulation, excessive perspiration in intertriginous areas, moderate leucopenia, a subclinical nutritional deficiency state, and a variety of skin lesions. The rationale of therapy must include the consideration of all these factors.

The nervous manifestations so characteristic of this disease are sluggishness, apathy and despon-

dency. These represent a vagosympathetic imbalance of the vagotonic type.

Any therapeutic measure that tends to calm the psychic state or reduce nervous irritability or tissue sensitivity is valuable whether it is bromides, barbiturates, calcium or one of the newer antihistamine drugs. The treatment of vitamin B deficiency is also important.

The basic pathologic condition consists of the triad of skin irritation, anospasm and lymph stasis.

Lymph stasis, which is caused by the slowing of peripheral circulation, allows the further accumulation of the irritating substance. Injection methods produce a phagocytic response and the phagocytic activity of the histiocytes produced by the reaction to these injections is known to remove toxins and protein particles, thus decongesting the peripheral lymph circulation.

Any rectal pathology which produces or intensifies rectal spasm should be corrected. The author uses the multiple puncture method of alcohol injection for itching. In the presence of scar tissue, redundant folds, pectinosis and marginal varicosities, surgical excision is performed and alcohol stippling is used to prevent recurrence of pruritus immediately following surgery.

Fungus invasion is aided by excessive perspiration and is signified by a linear abrasion or scaling in the intergluteal fold. The author uses boric acid ointment when irritation is extreme, and penetrating dyes to combat the fungus infection.

ERNEST D. BLOOMENTHAL, M.D.

Tattooing with Mercury Sulfide for Intractable Anal Pruritus. ROBERT TURELL. *Surgery* 1948, 23, 63.

The author presents an analysis of 93 (of a total of 106) cases of intractable pruritus in patients who had been treated by tattooing with mercury sulfide during the period from October, 1938 to November, 1942 and who had been followed personally and adequately for from 6 months to 4 years. At some time prior to tattooing all of these patients had received various forms of treatment without lasting benefit. The antecedent therapeutic procedures included topical medicines, endocrine drugs, irradiation, psychotherapy, subcutaneous injection of oil-soluble, long acting 'anesthetic solutions' or alcohol, anorectal operative procedures or combinations of these forms of therapy. The pertinent data concerning this group of patients are depicted in the accompanying tables.

Fifty-five of a group of 70 patients who had had chronic and recalcitrant anal pruritus associated with definite characteristic cutaneous changes have responded well to tattooing with mercury sulfide; the remaining 15 patients obtained 'satisfactory' results. Confirmation of this has been obtained in the treatment of vulval pruritus with cutaneous changes. Of 23 patients with similar complaints but who had no cutaneous changes consistent with chronic anal pruritus, only 6 obtained satisfactory

results while 17 showed no improvement. This too finds confirmation in the unsuccessful treatment by tattooing with mercury sulfide of vulval pruritus without cutaneous changes.

It appears that tattooing with mercury sulfide is an effective form of treatment for intractable anal pruritus which is associated with definite characteristic cutaneous changes in the absence of anorecto-colonic lesions. The patient who complains of severe anal pruritus but who has no cutaneous changes consistent with localized pruritus is in the majority of cases, an unfavorable candidate for this form of therapy. However, since no deleterious effects have to date, been observed following tattooing with mercury sulfide, this form of therapy may be given a trial in all cases of localized pruritus when more radical procedures such as the subcutaneous injection of ethyl alcohol or the radical excision of perianal or vulval skin are contemplated.

JOHN E. KIRKPATRICK, M.D.

Primary Postoperative Hemorrhagic Prophylactic Dressing in Anorectal Surgery. MARION C. PRUTTY. *Am J Surg* 94, 75 392.

The author has found a very practical use for oxycel. In the present article he discusses the application of oxidized cellulose gauze (oxycel) as an anorectal dressing. It is applied quickly to the oozing wound after sulfonamide powder has been meticulously rubbed in. A piece of 3 by 3 inch oxidized cellulose gauze is folded to make a right triangle. A forceps grasps the gauze and inserts it into the anus halfway. The outside half is spread over the external orifice. Two more pieces of oxycel 4 by 4 inches, are placed over this and a pressure dressing consisting of a perineal pad is applied over the gauze pack and fixed with tape across the buttocks. The dressing is used in operations such as hemorrhoidectomy, fistula, polyp, new growth or other operations within or without the anus. The dressing can be removed safely usually after a period of 24 hours without pain or bleeding.

STEPHEN A. ZIEMAN, M.D.

Treatment of Complete Prolapse of the Rectum. HERBERT T. HAYES and HARRY B. HURR. *Am J Surg* 94, 75 358.

The authors report 9 cases of rectal prolapse and its treatment. In 3 patients, nothing more than simple reduction of the prolapse was necessary; sclerosing agents were used on 3 others with good results. The last 3 were subjected to abdominal operation. In one case in which it was impossible to free the rectum or to expose the pelvic fascia, the peritoneum was brought under the rectum or to expose the pelvic fascia, the peritoneum was brought under the rectum as a new pelvic floor.

In operating on the last 3 patients the authors used the technique of Graham together with construction of a new bed for the sigmoid, which they have added. After administration of a spinal anesthetic, an ordinary rectal tube was inserted into the rectum for about

2 inches before the abdomen was opened. Beginning at about the level of the superior hemorrhoidal vessels the peritoneum on each side of the rectum was incised down to the level of the cul-de-sac and then completely across the cul-de-sac. Finger dissection then freed the rectum from the hollow of the sacrum down to the coccyx just as though removal of the rectum were contemplated. Blunt dissection then freed the rectum anteriorly. The defect between the levators could easily be felt. At this point Graham closed the defect by approximating the levators with sutures drawn through the pelvic fascia over the levators.

Both of the authors' patients were males in whom this procedure was found to be technically impossible. Instead of suturing the levators together they brought the lateral ligaments of the rectum across in front of the rectum and sutured these ligaments together with one or two linen sutures. This took up the slack in the overstretched lateral ligaments and prevented the anterior wall of the rectum from prolapsing through the defect between the levators and then with the rectum held up taut, the cut edges of pelvic peritoneum were turned under and sutured to the rectum at the sides and anteriorly. This obliterated the cul-de-sac of Douglas or the rectovesical pouch entirely. As a further support to the repair they made a new bed for the sigmoid by incising the lateral peritoneal leaf from the brim of the pelvis up the lateral gutter for a distance of 4 to 5 inches. After blunt dissection of the thin areolar tissue under the sigmoid the peritoneal leaf was sutured to the wall of the sigmoid while the latter was held up taut.

In none of these patients has it been necessary to tighten or do any plastic work on the sphincter muscles since in each case the muscles were competent.

JOHN J. MALONEY, M.D.

Modern Surgical Treatment of Hemorrhoids and a New Rectoplasty. A. GREGOR CARRICK. *Am J Surg* 94, 75 370.

The author states that the objective of hemorrhoidectomy is to remove all pathologic lesions and to restore normal anatomic configuration and normal function and to do so with a minimum of pain and morbidity.

The anal canal is an elastic tube surrounded in its entire length by voluntary muscle with a sphincteric action and contained within its upper two-thirds by the involuntary sphincter. It is lined by modified skin up to the semilunar valves and above them by mucous membrane. Connective tissue and epithelium regenerate but injured muscle is replaced by elastic fibrous tissue.

The removal of too much circumference, damage to muscle and fibrous replacement may cause stenosis. Seepage may be due to a downward displacement of the secreting mucosa. The early recurrence of hemorrhoids is usually caused by inadequate removal.

A complete histologic and digital and sigmoidoscopic examinations should precede surgery to rule

out the presence of neoplasms. Roentgen examination may be necessary to ascertain the condition of the upper reaches of the colon.

Preoperative preparation includes the administration of sulfathalidine 1 gm four to five times daily for 4 days before surgery and for 7 to 10 days after ward and a bland diet 24 hours preoperatively. Sedation is obtained by the administration of sodium pentobarbital $\frac{1}{2}$ gr the evening before surgery and if local or regional anesthesia is employed 1 hour before surgery. Morphine sulphate $\frac{1}{6}$ gr and scopolamine $\frac{1}{150}$ or $\frac{1}{200}$ gr is given hypodermically one half hour before operation.

The author favors spinal anesthesia which is produced by the injection of 20 mgm of procaine which also contains 1 to 20,000 suprarenin. This has given satisfactory anesthesia for one hour or more. The oil soluble reagents and diathane solution are also used to produce prolonged anesthesia and thus lessen postoperative pain. The Bue prone position with the buttocks elevated, either the left or right lateral position is preferred during the operation. Good surgery is most important to reduce postoperative pain.

The object of the surgical treatment of hemorrhoids is to produce a canal which will readily admit at least two fingers with the patient under anesthesia and one which is readily elastic and has a mucocutaneous junction which is no lower than the normal pectinate line that is 2 to 3 cm from the anal margin.

Radial excision is most frequently employed for simpler cases and has the advantage of leaving adequate islands of uninjured tissue. Extensive hemorrhoidal involvement requires circumferential excision, with the danger of ensuing stenosis. The author uses sliding skin grafts and occasionally anastomosis to prevent contractures. Relaxing incisions are used to allow the adjustment of skin to mucosa.

FIG 187 D. BLOOMSBURG, M.D.

Fig 2 (Carmel) Radical type (circumferential) hemorrhoidectomy with utilization of skin graft. 1. Three internal and external sutures are shown. 2. Titled lines indicate lines of excision on the hemispherical. 3. Depicts final result with skin graft and sutures employed for closure.

Fig 1 (Carmel) Diagram illustrating preparation of sliding graft and anastomosis in plastic repair of anal stenosis also employed to prevent contractures following radical hemorrhoidectomy. 1. Normal anal lumen. 2. A stenosed anal. 3. The anastomosis. 4. Separation of wound edges and consequent widening of anal tube. 5. Incisions for preparing sliding skin graft. 6. Graft has been drawn up to the entire surface of anal wound except for a narrow radiating. 7. Large open wound remains on outside far from margin. 7. End result.

Surgical Treatment of Chronic Ulcerative Colitis GARNEY W. ALLEN, M.D., J. S. W. G. 1945 75 325

One hundred and ten cases of chronic ulcerative colitis seen during the period from 1935 to 1946 are reviewed. Patients in whom the condition was classified as mild progressed favorably, but in 15 to 20 per cent of the patients the colitis had reached an advanced stage. The author deals with the treatment of this latter group.

Patients were classified as having chronic ulcerative colitis when they presented clinical, roentgen and proctoscopic features of this disease as described by Rankin, Bergen and Bue. The advanced stage was reached by an initial fulminating attack (most

conting wound closed. 1. Graft has been drawn up to anal canal and suture completed with sutures clearly shown in right side of illustration would easily be used without producing tension. 2. Final result with skin graft is shown.

A restoration to health and previous occupation was accomplished in 70 per cent of the patients.

EDMUND D. BLOOMFELT, M.D.

Primary Resection of the Colon and Rectum with Particular Reference to Cancer and Ulcerative Colitis. OWEN H. WASHINGTON and ROBERT W. TOOK, *Am. J. Surg.* 94:3, 751-754.

The improved record with reference to operative mortality has allowed surgeons to focus their attention upon the problem of the ultimate cure of cancer of the lower intestinal tract. The authors recount their experiences with primary abdominal resection of carcinomas of the rectum and rectosigmoid and their lymph node drainage areas, accompanied by re-establishment of intestinal continuity

In cancer of the colon the authors practice wide excision when lymph nodes are enlarged in the mesentery. When the left colon is involved it is almost completely removed from the splenic flexure to the sigmoid, and the transverse colon is anastomosed to the terminal pelvic colon. When indicated the greater portion of the entire colon is excised and an ileosigmoidostomy is performed to re-establish continuity. It is believed that more radical excision will produce more cures and less recurrence. Sometimes the transverse colon is mobilized for anastomosis to the rectum.

The authors present their results with anastomotic operation for rectal (within 13 cm. from the anus) and rectosigmoidal (between 13 and 30 cm. from the a. u.) lesions. Some cases of ulcerative colitis are included.

The operative technique employed was that of end to-end suture with a single row of interrupted silk sutures (No. 0000). A Lambert type stitch, spaced approximately 3 mm. apart, was used. Anastomosis was performed as low as 3.5 cm. from the anal orifice. The abdominal pull through operation with complementary colectomy (to be closed later) was performed rarely.

The anastomotic method which preserves the sphincter is a more conservative operation. It is too early to assess the results definitely. However restitution of intestinal continuity may be performed as a one-stage operative procedure after excision of the terminal pelvic colon and upper rectum, with a hospital mortality comparable to that attending performance of the abdominoperineal operation. Functional sphincteric control is complete after the suture operation. The sphincteric control is not quite as good following the abdominopelvic pull through operation and the healing phase in this operation is much longer. The preservation of the internal sphincter insures continence.

In lesions of the rectosigmoid local recurrence has not followed primary resection with anastomosis. However, the incidence of local recurrence following conservative procedure for lesions at 8 cm. or less from the anus is frequent enough to suggest that sphincter-saving operations are contraindicated in all low-lying lesions. In the middle rectal segment or rectal ampulla above 8 cm., the conservative operation is a satisfactory operation for suitable cases and holds out to such patients approximately the same promise of cure as does the more radical abdominoperineal operation. For dubious lesions in this area the abdominoperineal operation is the procedure of choice.

Local recurrence occurred more often in lesions at 8 cm. or less from the anus and the remainder of recurrences were in lesions at between 9 and 13 cm. from the anus. In the entire group, local recurrence was observed in 7 of 51 cases (14%). Local recurrence was almost invariably outside the anastomotic area and the percentages compare favorably with the radical abdominoperineal resection.

Unsuspected polyps were frequently found in a more proximal segment of the colon. As polyps are precursors of cancer of the colon, it is suggested that wider and more radical excisions may be productive of more cures.

The anastomotic procedure was employed with some success for extrinsic rectal tumors and for ulcerative colitis. Satisfactory rectal continence and preservation of normal sex function is quite uniform after performance of resection with end to end anastomosis.

FRANK D. BLOOMFELD, M.D.

Production of Allergic Gastric and Duodenal Edema which Predisposes to the Histamine-Provoked Ulcer in Dogs. STANLEY R. FAIRBANK, DAVID STARR, DONALD L. JAMPER, MINNIE FINE, and OWEN H. WANGENSTEEN. *Surgery* 1948 23 167.

The authors report a method of experimentally producing prolonged gastric and duodenal edema in dogs on an allergic basis. The animal was sensitized systemically and locally (stomach and duodenum) by the local injection of antibodies, followed later by the systemic administration of antigens.

It was determined that local gastrointestinal edema with alteration of the general condition of the dog favors the development of the histamine-provoked ulcer and that local anaphylaxis produced by passive local sensitization of the gastric or duodenal mucous membrane with local antigen-antibody reaction aggravates the ulcer diathesis.

ROBERT T. RILEY, M.D.

Jejunitis Acuta—Histiocytic Regionalis Acuta. B. CHURCHMAN. *Lancet* 1948 2 351.

The author describes 21 cases of acute jejunitis in 16 cases of acute regional ileitis. These conditions are believed to be the same complaint with different localizations. In the opinion of the author, acute jejunitis occurs more frequently than is generally supposed. In most cases one may arrive at a correct diagnosis with the aid of roentgenographic examination.

Jejunitis may be divided into two forms—acute phlegmonous jejunitis which carries a heavy mortality and a light mild form which the author suggests should be called acute jejunitis. This last form is little known and may frequently be undiagnosed. Jejunitis may be followed by stricture which has often been described in the terminal part of the ileum.

The cause of the complaint is believed to be infection from the intestine with further spreading to the submucosa or possibly through the lymphatic channels. Bacterial microbe are believed to be of importance as a source of the infection.

The author emphasizes the importance of bacteriological examination and also of follow up examination of the patient.

JOHN J. MALONEY, M.D.

Pathophysiology of Peptic Ulcer. A Clinical Study of 115 Cases Treated with Ergotamine. *Acta Medica Scandinavica* 1947 120 Supp. 202.

Ulcer disease is one of the strangest and most puzzling diseases known to internal medicine and in addition has an extremely high frequency. For these reasons it is only natural that ulcer disease should have been the object of close study. Numerous theories supported by clinical and experimental data have been formulated to explain the cause of ulcer. Hitherto, however, no satisfactory final answer has been given to the question of the pathogenesis of ulcer disease. It seems, however, to have been proved that ulcer disease is a syndrome, the manifestations of which appear in different parts of the organism and that the peptic lesion in the intestinal canal is only one of the symptoms.

From the clinical facts and experimental data for ulcer disease, liver metabolism and carbohydrate metabolism, a penetrating analysis has been made in order to throw light on the pathophysiology of the disease and thereby decide upon an adequate method of therapy.

According to this analysis, the belief has been expressed that ulcer disease originates in a biological extreme variant and is characterized by a high reactivity in the sympathoadrenergic centers of the hypothalamus with its consequent effect on the individual under stress of external factors which influence the sympathoadrenergic system such as a general disturbance of the metabolism with displacement towards acidity with the following results: gastric hypersecretion, impairment of the homeostatic mechanism of the liver and a disturbed sugar metabolism, direct influence on the alimentary tract with gastric hypomotility, pylorospasm and a general increase in the output of hormones together with intestinal atony, a vasoconstriction within the plastric region whereby follows a distal vasospasm of the mucous membrane, a direct influence on the marrow of the suprarenal glands, a hypersecretion of which intensifies the other disturbances, a stimulation of parasympathetic centers provoked by the disturbed sugar metabolism resulting in a far beyond a postabsorptive secretion and an ulcer secretion.

These last symptoms are facultative, due to the degree of severity of the primary disturbance, and are considered as compensatory.

The combination of these factors produce in the stomach or duodenum the local manifestation of ulcer disease.

With regard for this hypothesis, and on the basis of the knowledge of the pharmacodynamic properties of ergotamine, this substance has been used in the treatment of 115 patients with ulcer. The author's series comprised both ambulatory and clinical patients. The guiding principle has been to give only ergotamine and to dispense with other therapeutic measures, e.g. dietetic restrictions, confinement to bed, etc.

The results of the treatment have been controlled by roentgenograms. In a certain number of cases oral tests have been made of the glucose tolerance before and after treatment. Following treatment with gylgergen the patients become rapidly symptom-free. It is easy to treat the ambulatory patients and recurrences can be prevented by immediate intervention as soon as the initial symptoms appear.

HARRY W. FOXE, M.D.

Primary Nonspecific Ulcers of the Small Intestine

JOHN A. EVERET, R. MARDEN BLACK, and BLAISEL B. DOCKERTY *Surgery* 94:8, 3-85.

Nonspecific localized ulcerations of the jejunum and ileum are so similar pathologically as to justify their classification as a group under the name "primary" or simple ulcers. Although the lesions are characteristically solitary, small groups of ulcers are sometimes found. The etiology of primary ulcers is unknown. There is little direct evidence to support the theories that they are caused by infection, irritation from gastric secretions, trauma, or vascular abnormalities.

The symptoms of primary ulcer are for the most part secondary to the complications of perforation, bleeding, or obstruction. The possibility of these lesions should be considered in the presence of unexplained intestinal bleeding or of peritonitis which suggests acute visceral perforation when such perforation cannot be found in the stomach or duodenum.

The mortality rate in patients suffering from primary ulcer is high. The lesion has been recognized during life only after some complication has led to surgical intervention.

Bleeding Peptic Ulcer CHARLES BAKER. *Guy's Hosp. Rep.* Lond., 1947, 96

The author presents a clinical study of 576 patients with bleeding peptic ulcer who were admitted to the Selly Oak Hospital, Birmingham, England, during the 6 year period from 1940 to 1945. Only those cases in which there was bleeding on or after admission and in which bleeding was from a peptic ulcer were included in the series. If these two points were established no standard of severity on admission was necessary.

The mortality rate was 13.4 per cent. If 5 patients dying as the result of perforation complicated by bleeding are included the mortality rises to 14.1 per cent. Taking into account the undoubted improvement in treatment in recent years, and the greater readiness and ease with which blood loss can be overcome, this figure is undoubtedly high. According to the author two important factors are responsible for this: the large proportion of patients arriving in very poor condition and dying within 24 hours, and the large number of patients in the high age groups. Comparing this mortality record with that of the preceding 6 year period brings up an interesting observation. From the years 1934 to 1939, the mortality from bleeding peptic ulcer was 7 per cent in the same institution. It is possible that the increase in mortality was due to the physical and mental strain of the war and the bombings in Birmingham. Coincident with this increase in mortality from bleeding ulcer there was a concomitant increase in the incidence of peptic ulcer in general.

A review of the time of year at which fatal hemorrhages occurred showed that there was no particular season when this was strikingly common though there was a slight decrease in late spring and early summer. Further analysis of factors underlying the problem of bleeding peptic ulcer indicated that peptic ulcer is not only more difficult to diagnose than duodenal ulcer, but that it is more likely to bleed and cause death from bleeding. This is an important point in prognosis in the individual case.

Treatment varied with each case but, in general, the plan was somewhat as follows: rest, physically and mentally; fluid replacement and blood transfusion for severe loss; early feeding; and if these medical methods fail or seem likely to fail, early recourse to surgery before the general condition deteriorates. Previous writers on hematemesis have deplored the fact that important decisions in cases of bleeding ulcer were left to juniors. In this series the cases have been under the individual care and direction of a small group of three full time physicians so that there is no great divergence in the methods adopted and treatment of the patients in the series is reasonably uniform.

The question of radiography after bleeding is a serious one until there is a reasonable chance that the bleeding point is healed, the danger of restarting a hemorrhage must be considered. The author believes that the hemoglobin should be at least 60 per cent, the occult blood test negative, and the patient should be well enough to be out of bed before roentgenograms are taken. Six deaths from hemorrhage occurred shortly after roentgenography, the interval being 1, 4, 6, 9, and 13 days between roentgenography and the first subsequent bleeding.

To classify the problem of the place of emergency surgery in the treatment of bleeding peptic ulcer was one of the main objects of this investigation. Though the proportion of patients operated upon was small, a comparison between those selected for surgery and those not selected, between successes and failures

seen against a background of a large number treated by medical methods alone yielded some valuable information. The surgical mortality reflects the physician's principles as well as the surgeon's difficulties. There is no more satisfying result than successful intervention for it is the result of combined judgment, skill and teamwork.

As the result of an extensive analysis the author has come to the following conclusions regarding the indications for surgery:

Before a decision to operate is considered three essentials must be present: reasonable clinical evidence that a chronic ulcer is present, failure of medical treatment provided this has been adequate, absence of intercurrent disease. Given these three points the indications for operation, apart from definite emergencies such as perforation, seem to be:

1. The presence of an obstructive factor. With associated pyloric stenosis or hour-glass deformity, operation should be considered after one severe hemorrhage or persistent bleeding even if minimal.

2. Sudden hemorrhage while under medical treatment for an ulcer if the patient was admitted without bleeding, particularly if pain has not been relieved by strict regimen in bed.

3. Recurrent hemorrhage while under good medical treatment for bleeding. After the first attack while under treatment, operation should be considered if there is no response within 24 hours to renewed emergency measures. After the second attack it should be considered seriously whatever the response. With succeeding hemorrhages the indication is increasingly strong. The longer the interval between the recurrent bleedings and the better condition in the intervals, the longer can the surgery be delayed but the more certain it is that operation will ultimately be needed.

4. Persistent bleeding as indicated by the general condition of the patient even if unassociated with further hematemesis or melena. In these cases delay is dangerous. In the absence of absolute indications for operation, the best time for a decision is the fourth or fifth day and it should not be delayed longer than a week. A reasonable decision can rarely be made in the first 48 hours. The need for operation in acute ulcer seldom arises and a surgeon should rarely be asked to operate on other than a chronic ulcer.

HAROLD LAUFMAN, M.D.

Treatment of Peptic Ulcer. RUSSELL S. BOLES.
J. Am. M. Ass., 1948, 136: 528.

The author believes there is an immediate need to abolish the term "peptic ulcer." No proof exists that the ulcer is due to peptin. The ulcer itself is no more the disease than an ulcer on the toe is diabetes or Buerger's disease. Hyperchlorhydria does not cause peptic ulcer; rather the ulcer causes hyperchlorhydria, the latter being the result of pylorospasm with food retention and irritation of the gastric glands.

The highly unsatisfactory results of medical and surgical treatment of ulcer can be attributed to the

failure to investigate the influence of social, genetic, environmental and domestic factors which may be related to the incidence of the disease. There may be present an ulcer diathesis which renders certain types of persons because of psychological and physical characteristics more susceptible to ulcer.

The crux of the ulcer problem is the cell resistance of the gastric mucosa. Cellular resistance probably depends on the state of the circulation in the stomach, and on the chemical composition of the blood reaching the cells. Chronic circulatory insufficiency in the deeper layers of the stomach—possibly the result of blood vessel spasm—exerts a significant influence in ulcer formation. The effect of emotional disturbances on the circulation of the stomach leading to mucosal erosion and hemorrhage have been described. The effect of tobacco in ulcer production may logically be attributed to its action on the end vessels in the stomach and duodenum.

Peptic ulcer is a medical problem. Operations should be reserved for the complications of perforation, hemorrhage, obstruction and so-called intractability. The unsatisfactory results of medical treatment can be charged to preoccupation with the correction of the chemical environment of the lesion. While acidity may be controlled by rest, diet and a calm life, healing and recovery appear to be the result primarily of release of pylorospasm and vascular spasm in the gastric vessels.

The employment of extracts, hormones or other substances by injection for the treatment of ulcer is analogous to the use of insulin in diabetes. Any benefit from such treatment is probably temporary.

The intragastric drip is effective in reducing acid secretion and is well suited to refractory ulcers with a high continuous nocturnal secretion, especially when pyloric spasm is present. The various protein hydrolyzates and amino acids do not exert any specific influence on ulcer as supplements to the diet; they are useful.

That gastric resection is not the answer to the ulcer problem may be suspected from the widely varying statistics concerning its results and the diversity of opinion as to what the method and the extent of the procedure should be. Resection for benign gastric ulcer carries more promise of relief and protection from recurrence than resection for duodenal ulcer. Resection for hemorrhage appears to have little to offer in the general run of cases.

The treatment of ulcer by vagotomy and a consequent reduction in acidity disrupts the secretory and motor mechanisms of the stomach.

A model plan of life for patients with ulcer not only would promote healing but would minimize the risk of complications and recurrence in most cases. It should be undertaken however with the understanding on the part of the patient that infraction of the rules means recurrence. Ulcer should be regarded as an incurable disease; it may be held in check, however, by the cultivation of a new manner of living. In occasional cases in which the ulcer is adherent to other structures or is so sclerotic that no

medical measures can hope to hold promise of recovery surgical intervention becomes necessary. Under these circumstances, it is advisable to perform as conservative an operation as possible.

SAMUEL KANZ, M.D.

Vagotomy for Peptic Ulcer HENRY N. HARRIS and DONALD H. HOOKER. *Surgery* 947 : 239.

The operation of vagotomy for peptic ulcer has been widely used since its revival by Dragstedt and Owens in 1933. The modern procedure differs from most of its predecessors in that it is undoubtedly more complete and is performed only near the level of the diaphragm. Two approaches are used: the transthoracic and the transabdominal.

In the laboratory 5 types of experiments were done. Three of these showed no effect of the test procedure on the incidence of histamine-provoked ulcer in the guinea pig. These negative experiments included transabdominal vagotomy, the administration of aqueous benadryl solution by mouth and the subcutaneous administration of benadryl in beeswax.

Two other types of experiments gave more positive results. Beaver and Mann reported that 3 control Mann-Williamson dogs developed ulcer (100 per cent) whereas of 3 such dogs with supplementary transthoracic vagotomy only 2 developed ulcer (67 per cent). It was thought advisable to repeat this experiment with a larger number of animals. In the authors' series of 3 control Mann-Williamson dogs 12 animals died with ulcer (85 per cent) after from 29 to 161 days following the operation. Two dogs dying 55 and 145 days respectively after the operation had no ulcer. In the series of 9 dogs subjected to the Mann-Williamson operation plus a supplementary transthoracic vagotomy only 1 died with ulcer (11 per cent) 41 days after operation. Six of these dogs died from 28 to 97 days following the Mann-Williamson operation and prevented no signs of ulcer. Two additional dogs with the combined procedure were still alive 206 and 430 days respectively after the Mann-Williamson operation. In the control series no animals were included unless they lived at least 4 weeks after the operation.

Shay and associates reported in 1935 that within 15 hours of pyloric ligation rats, which had been previously starved regularly, develop multiple hemorrhagic ulcerations of the gastric mucosa. In some instances ulcers of the fundus were also observed. The effect of vagotomy on the development of such ulcers has not been previously reported. The vagotomy was done infradiaphragmatically by a modification of the method by which Heymanns of Chent used to ligate the nerves to the carotid sinus. Following the operation the animals were either sacrificed at the end of 24 hours or kept alive as long as possible with almost daily injections of from 10 to 15 c.c. of glucose-saline solution. In the control series of 17 rats all of them had ulcerations of the gastric mucosa and 7 of them had in addition ulcers of the fundus of the stomach. There was a total of 346 ulcers or an average

of 22 ulcers in the mucosa of each rat. Histologically the ulcers were deep, some involved most of the layers of the stomach wall, and there was an associated extensive edema. In the stomach there was an average of 14 c.c. of fluid showing 17 units of free acid and 81 units of total acid. The series of 15 vagotomized rats showed no ulceration of the mucosa nor fundus, nor edema of the stomach wall grossly or microscopically. There was an average of 7 c.c. of fluid in the stomach with a free acid of 7 units and total acid of 56 units. As to survival, 6 rats with pyloric ligation alone lived an average of 46 hours, whereas those with a supplementary vagotomy survived an average of 97 hours. Irrespective of whether the lesions produced by pyloric ligation are ulcers or deep hemorrhagic erosions, they are prevented by vagotomy during the time limit under discussion. Diminished gastric volume and acidity are not the only factors concerned in the beneficial effect of vagotomy.

Vagotomy of the modern type was performed on 36 patients with peptic ulcers. The cases fell into several groups so that a variety of procedures were performed in association with vagotomy. However, the authors state that it can be said very tentatively that the vagotomies performed with shunts or gastric resections have on the whole given better results than those when no complementary procedure was performed. They classed 4 cases in the series as clinical failures because the insulin test was negative and another operation was necessary. In 3 of these the vagotomy was not complete. In 3 of the patients ulcers were found.

The triad of symptom changes following vagotomy are relief of pain, relative diarrhea, and delayed gastric emptying. EDWIN W. PARMARILL, M.D.

Experiences with Vagotomy for Peptic Ulcer RICHARD WARREN. *Surgery* 947 : 246.

A series of patients was studied in a large veterans hospital. The incidence of peptic ulcer over a 3 year period was 6.7 per cent. This figure is considerably higher than that reported from civilian hospitals. The highest figure in the literature on the incidence of peptic ulcer among admissions to civilian hospitals is 4 per cent. The probable explanation for this is that in the veterans hospital there is an exclusively male population.

Vagotomy was performed on 15 patients with duodenal or stomach ulcer. Patients for operation were selected largely on the criteria of Dragstedt and of Moore and associates: young patients, uncontrolled by medical therapy, who had a high degree of stress sensitivity, a gastric secretion high in acid and a copious amount of night secretion, and who presented no problem of cicatricial pyloric obstruction. These criteria were expanded to include other patients who needed surgery for duodenal ulcer. In order to maintain a consistent policy in their first cases, the following were used as contraindications for inclusion in this series: recent massive hemorrhage in patients over 45 years of age or active bleeding at the

time of surgery at any age diagnostic uncertainties produced by conflicting roentgenograms obviously poor mechanical situations resulting from ill-adviced previous surgery and pyloric obstructions. Under these criteria may be included some of those intractable cases in the middle age group without copious night secretion and others with chronic alcoholism, Buerger's disease and psychoneurosis.

The transthoracic route was used in all but one case and the Moore modification of Dragstedt's technique was employed. The early complications noted following operation included minor atelectasis in one patient and contralateral pneumothorax and mediastinal emphysema in another. Ten patients had considerable postoperative hyperpyrexia from 101 to 120 F for 3 or 4 days. Most of them had annoying postoperative chest pain. One developed subdiaphragmatic abscess. Three patients developed symptomatic postoperative gastric retention. Two of these had one episode of vomiting. The third suffered exacerbation of a duodenal ulcer and developed 2 gastric ulcers in addition. The results of operation show that after recovery from the complications all but 3 of the patients are clinically well from 1 to 8 months postoperatively. Of the 3 2 have a gastric retention manifested by vomiting once or twice a week, the third patient is the one with flare up of the duodenal ulcer and the additional gastric ulcers. A successful gastric resection was done 7 weeks after vagotomy.

The author discusses the latter case in detail. This patient had Buerger's disease and a mild addiction to alcohol in addition to his ulcer. Following vagotomy the patient did very well for 3 weeks. Evidence of adequate vagus interruption was shown by the insulin test; however the fasting acidity was higher than before operation. Clinical symptoms supervened in a short time and gastric resection was performed 7 weeks after vagotomy with complete success. The specimen showed 2 gastric ulcers and no evidence of disease of the arteries.

A theoretical explanation for this situation is offered. It being kept in mind that changes occur following vagotomy and also that vagotomy will cause gastric ulcers almost routinely in the rabbit and occasionally in the dog and monkey. Because of vagotomy the importance of the cephalic phase of gastric secretion has been greatly emphasized. It is logical to suppose that there are patients with peptic ulcer whose hyperacidity is the result of the gastric phase of gastric secretion. Neutralizing factors in patients with hypersecretion are the gastric mucus and the regurgitated alkaline duodenal juice. Although Ferguson has shown there is some mucus still present in the juice of a vagotomized stomach, Babkin has demonstrated that the vagus juice is moderately rich in mucus whereas the histamine juice has little. It is undeniably possible that in certain ulcer patients the gastric phase of gastric secretion contributes more to the hyperacidity than the cephalic phase. In these patients removal of some of the alkaline mucus by vagotomy especially

if there were enough pyloric obstruction to prevent duodenal regurgitation might render the gastric mucosa more vulnerable to ulceration.

EDWIN W. PASSARELLI, M.D.

The Operative Treatment of Chronic Gastric and Duodenal Ulcer. CHRISTIAN BAUGAARD. *Surg* 1948 43 161

The authors' experience with the surgical treatment of chronic gastric and duodenal ulcers is reported. Gastrojejunostomy was performed on 476 patients with a mortality rate of 4.7 per cent, while partial gastrectomy was employed in 573 patients with a mortality rate of 4 per cent. Bruugaard believes that gastrojejunostomy should not be used as the routine method for the treatment of chronic gastric and duodenal ulcers; partial gastrectomy is the therapeutic method of choice for these lesions. In patients with duodenal ulcer who are over 60 years of age, gastrojejunostomy yields the same results as partial gastrectomy. Gastrojejunostomy is especially useful for patients in this group whose general condition is poor or in whom technical surgical difficulties are encountered which might increase the operative risk.

ROBERT TURELL, M.D.

Thirty Nine Cases of Total Gastrectomy (A propos de trente-neuf observations de gastrectomie totale). R. DE VERNEJOUL. *Lyon chir* 1948 43 17

In a great number of articles published during the last 15 years in different countries, the postoperative mortality of total gastrectomy varied from 14 to 60 per cent. The author discusses a series of 39 of his own cases. 30 of the patients had carcinoma, 4 juxta-cardiac ulcer and 5 recurrent peptic ulcer after one or two preceding gastrectomies. Ten of these patients died immediately after surgery, 6 developed recurrences or metastases and 1 was lost to sight. Twenty-two are living 15 for more than a year after the operation.

In the patients who survived the operation, an initial period of gastro-intestinal disturbances (diarrhea, nausea, vomiting) was followed by good adjustment, hearty appetite, and gain of weight. The digestion of protein and carbohydrates appears normal whereas the assimilation of fat is not satisfactory according to many authors. Development of pernicious anemia due to gastrectomy has not been observed in any of the author's cases.

The questions of indication and surgical technique are discussed briefly. The main indication is carcinoma, whereas in cardiac ulcer and in recurring peptic ulcer vagotomy may be preferable as an alternative. As to technique the author prefers the method of Lefevre after resection of the xiphoid cartilage a loop of jejunum is sutured to the inferior surface of the diaphragm and the afferent part is used as a peritoneal sac which covers the site of the anastomosis from all sides. This procedure prevents disunion of the sutures and leakage at the anastomosis with ensuing fatal peritonitis which is the principal danger. WERNER M. SOLMETS, M.D.

The Gastric Secretion after Subtotal Gastrectomy for Ulcer. A Study Comparing the Reduction of Secretion after Gastrectomy and after Vagotomy (*Sécrétion gastrique après gastrectomie subtotale pour ulcère. Étude comparée de la réduction de la sécrétion après gastrectomie et après vagotomie*). P. SARTY, P. MARROW, J. MELEY and S. SCHMUCK. *Lyon chir.* 948 43 60.

Most statistics report that after subtotal gastrectomy the secretion of hydrochloric acid usually stops and the gastric juice reveals achlorhydria.

The authors, in a series of 31 cases, obtained less favorable results. In 16 (52%) of their cases the gastric stump secreted hydrochloric acid, either in the fasting patient or after the injection of histamine. In order to obtain correct results it is important to make sure that the sample of gastric juice does not contain bile. The reflux of bile into the stomach may falsify the picture as bile neutralizes free acid. Furthermore, it is important not only to perform the test immediately after the operation but to repeat it some months later. Several cases are on record which showed absence of free acid shortly after the operation but recurrence of acidity months or even years later.

The volume of gastric juice is reduced by about 50 per cent after subtotal gastrectomy; the average hourly volume being 133 c.c. before, and 76 c.c. after the operation.

The authors believe that recurrences of peptic ulcer after subtotal gastrectomy can occur only if the stump secretes free acid. Six of their cases were of this kind.

On comparing the results of bilateral vagotomy with those of subtotal gastrectomy the authors found that the decrease in the volume of gastric secretion is about the same after both procedures, but the reduction of free acid is more marked after gastrectomy. The two methods may be combined in appropriate cases in order to prevent or to treat postoperative peptic ulcer.

WERNER M. SOLMITEZ, M.D.

Intestinal Ulceration Due to Arterial Necrosis (Malignant Hypertension and Polyarteritis Nodosa). S. DE NAVARRETE and E. B. FREEMAN. *G. S. Hosp. Rep. Lond.*, 1947 96 85.

Intestinal ulcers are uncommon manifestations of arterial necrosis due either to malignant hypertension or to polyarteritis nodosa. The authors present a case in which the clinical picture indicated predominantly intestinal involvement.

The first case was that of a young female, age 33 with a short history of 3½ weeks' illness with intestinal hemorrhage and malignant hypertension. Sudden collapse of the patient was due to hemoperitoneum, but she died before a laparotomy could be performed. Postmortem examination revealed irregular serpentine ulcers in the lower portion of the ileum. Microscopic examination of the ulcerated areas showed denudation of the mucosa and submucosa and interruption of the muscularis mucosae,

which were replaced by a fibrinocellular exudate. The small arteries and arterioles of the submucosa showed every degree of change from an acute inflammation of the adventitia and media to complete necrosis of the entire wall, the vessel being reduced to a mass of fibrin containing nuclear debris and an occasional leukocyte. The same lesions were found in the kidneys, but were far fewer in number.

The second case was that of a female, age 57, with a 3 months' history of diarrhea and a spurlie syndrome. Despite transfusions and medical treatment for a severe anemia, the patient died. At autopsy the ileum showed ulceration of varying depth, from superficial necrosis and desquamation to disappearance of the entire mucosa and submucosa. This was accompanied by an inflammatory reaction in the underlying wall which varied from an acute fibrinocellular exudate to a chronic granulomatous reaction which caused thickening of the wall. The inflammatory reaction was predominantly vascular being related to corresponding changes in the arteries, arterioles and venules. There was necrosis of the vessel wall involving particularly the media and adventitia and occasionally the intima. In the most severe examples the vessel was replaced by a ring of amorphous eosinophilic material containing nuclear debris and surrounded by leukocytes. The jejunum was less severely affected and the lesions were more granulomatous in type. The spleen showed numerous foci of ischemic necrosis. In some of these the eosinophilic outline of necrotic vessels could be seen, while in others of more recent date a necrotizing arteritis was present. A similar type of necrosis was found in the mesenteric lymph glands.

HAROLD LAUFMAN, M.D.

Cancer of the Rectum. FRED W. BAXTER and COLLEMAN C. JOHNSON. *J. Am. Med. Ass.* 1948, 35: 371.

Rectal cancer is easily diagnosed and radical surgery offers the most favorable prognosis. There is considerable controversy over the type of procedure most acceptable in the majority of cases. Miles made the greatest contribution in this field of surgery and an improvement on the combined abdominoperineal resection has yet to be found.

Many procedures have been developed for the preservation of the anal sphincter but in the light of recent anatomic studies of the lymphatics of the perirectal and pelvic tissues these are of little value.

The grade of malignancy of the lesion and the presence or absence of glandular involvement exert a profound influence on prognosis. Hence, the basic surgical principle should be to use as radical an operation as possible with widespread removal of gland-bearing tissue.

The secret of adjusting to an abdominal colostomy is the realization that this is the safest method of insuring longevity. Uncertainty on the part of the surgeon that a colostomy is essential leads to hesitation, dissatisfaction, and maladjustment. Careful explanation prior to surgery, early routine colostomy care, and firm instruction and encouragement do

much to hasten the psychic readjustment of even the highly emotional and unstable patients.

The authors favor the Miles combined abdominoperineal resection in one stage because (1) it permits ligation of the blood supply to the pelvis before the pelvic dissection is carried out (2) it permits wide spread removal of gland bearing tissue in all zones of spread and (3) it gives a higher percentage of 3 and 5 year cures and more freedom from recurrence than any other procedure. The authors discuss the disadvantages of other less adequate procedures.

Preoperatively the nitrogen, caloric, and electrolyte balance should be restored as the patient's physiologic reserve is important in keeping down mortality. Careful preoperative bowel irrigation, sulfanamide transfusions, vitamins and penicillin are used routinely.

The authors review their experiences with 336 cases of rectal cancer. Seventy five per cent of the patients were resectable and in 167 the one stage combined abdominoperineal resection was carried out with a mortality of 5.3 per cent. The 5 year survival rate was 52.4 per cent. Glandular metastases were found in 73 patients. 89 had no glandular involvement. The former group had 2 times the number of 5 year survivors that the latter group had.

There was a high incidence of death due to small bowel obstruction. The authors stress this complication. They urge early reoperation.

Early diagnosis to increase the rate of resectability is the present goal. ROBERT R. BROWNE, M.D.

Carcinoma of the Rectum and Rectosigmoid. A Statistical Analysis of 844 Cases. RALPH A. THOMAS, PHILIP S. KLINE, and LINDON SEED. *Arch Surg.*, 1948, 56, 93.

The authors reported a statistical analysis of carcinoma of the rectum and rectosigmoid in 844 men who were admitted to the Veterans Administration Hospital, Hines, Illinois from 1931 to 1946. The frequency of the most important symptoms in 400 of these patients expressed in percentages is as follows: (1) bleeding 76.5, (2) loss of over 10 pounds in weight 67.2, (3) diarrhea 40.5, (4) pain in the rectum 24.7, (5) constipation 23.1, (6) abdominal pain 12, (7) small stools, 5.2, (8) alternating constipation and diarrhea, 5.1 and (9) acute obstruction 3 per cent.

Bleeding as the first symptom occurred in 36 per cent of the cases. Twelve per cent of the 400 patients had had antecedent treatment for hemorrhoids, most of them having undergone hemorrhoidectomy. Internal and external hemorrhoids are believed to be the result of obstruction of venous drainage produced by the cancer high up in the rectum. Parenthetically, with few exceptions the rectal malignant lesion in these cases can be recognized on digital examination alone.

Loss of weight, contrary to the general opinion, occurs early in the course of the disease.

A change in bowel habits in the form of either diarrhea or constipation or both was present in 73.8

per cent of the patients, the diarrhea being more frequent than the constipation. A history of alternating diarrhea and constipation a supposed frequent accompaniment of rectal cancer was obtained in only 5.1 per cent of patients.

Abdominal pain usually attributed to partial obstruction was found in 12 per cent. In 2 patients appendectomy was performed for this type of pain.

In the decade from 1931 to 1940 the duration of symptoms from the alleged time of the onset of illness until the patient presented himself for examination was 11.3 months. In the period from 1940 to 1946 the time interval dropped to 9.7 months. The median for both groups was about 7 months that is one half of the patients presented themselves before, and the other half after the symptoms had persisted for 7 months. There is little correlation between the duration of symptoms and operability and resectability of the lesion. The duration of symptoms was practically identical for the various age groups.

There were 13 anaplastic or undifferentiated carcinomas and 743 adenocarcinomas. There were 10 malignant polyps which also showed adenocarcinoma. The authors surmised that many more adenocarcinomas had their origin in a pre-existing polyp. The incidence of epidermoid or squamous cell cancer was low — 0.7 per cent.

The authors reported a doubling of the resectability rate which began in 1940 and was accompanied with a sharp reduction in mortality for all procedures. This improvement is ascribed to increased surgical experience and better preoperative preparation with special reference to the maintenance of the fluid, electrolyte and protein balance, the more liberal use of blood and plasma, and the use of the sulfonamide drugs and antibiotics in the control of infections.

Colostomy prolongs the life of the patient who has an obstructing lesion but it does not prolong life much beyond that of the patient with a nonobstructing lesion. Adequate irradiation prolongs life and should be used as a palliative procedure and as a prophylactic postoperative measure. Patients surviving abdominoperineal resection had a 45.5 per cent chance of living 5 years. There is little difference between the survival curve for the two stage perineal excision and that for abdominoperineal resection for the first year but after that the latter procedure is at a higher level. Patients surviving a perineal excision had a 32.1 per cent chance of living 5 years.

As a result of their studies the authors believe that carcinoma of the rectum or rectosigmoid should be adequately resected. The operation should be carried out even in the most adverse circumstances.

ROBERT TOWELL, M.D.

The Closure of Colostomies. GEORGE B. SANDERS, HEINZ HARTNER, and ROBERT B. LYNN. *Ann Surg.*, 1948, 127, 243.

Experience with 72 consecutive colostomy closures has resulted in a decided preference for a method of colostomy closure which will provide

Fig. (Sanders et al) Pouchet technique of colostomy closure. Caution is not used in modification of this procedure. Colostomy stoma and adherent skin cuff are excised with scissors. Vertical incision in long axis of each loop of limb is made also with scissors, from stoma down and instead of as shown. The continuous suture shown in 5 is usually continued down the lateral aspect of the anastomosis as continuous Connell stitch. Interrupted Halsted sutures of fine black silk are substituted for continuous Lembert suture shown in 6. (Reproduced in *Annals of Surgery* by permission of publisher from Malcot *Abdominal Operations* D Appleton Century Co. New York.)

As early anatomic a reconstruction of the colon and abdominal wall as is possible namely an intraperitoneal type of closure.

2. A technique of closure which offers the least age of time and the not too remote dangers of infection and a preliminary spurting of procedure.

3. A type of intestinal anastomosis which will allow the surgeon considerable freedom in suturing so that he may make a two-layer or even three-layer

closure of great firmness, turning in a sufficient cuff of bowel wall to ensure excellent peritoneal coaptation yet at the same time leaving a sufficiently large lumen at the site of closure which will not under any circumstances become stenotic due either to immediate postoperative edema, or to its later occurrence from cicatricial contraction.

In the main end-to-end anastomosis, with or without actual resection of the colostomy itself satisfies

these requirements fairly well. Nevertheless it has been the authors' experience in a significant number of cases that with this method immediate postoperative edema has sufficiently compromised an otherwise adequate lumen so as to endanger the integrity of the suture line or to cause postoperative discomfort, cramps and other nuisances. Consequently their decided preference is for the Panchet type of closure which they have come to employ almost exclusively for the closure of colostomies in the transverse, descending and sigmoid colons. In their experience with this type of closure withholding of food postoperatively is unnecessary, postoperative discomfort is minimal and early ambulation is accomplished readily. Wound infection, leakage or failure of the closure and obstructive symptoms either early or late are thus far unknown.

JOHN J. MALONEY, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

A Study on the Abolition of the Sphincter of Oddi
(Studio sull'abolizione dello sfintere di Oddi) MARIO
NEGRI and GUIDO CASTRINI *Arch. ital. chir.*
1947 69 385-392

A review of the literature discloses that there are divergent and even contradictory opinions regarding the anatomy and physiology of the sphincter of Oddi.

In 1653 Glisson supposed that there was a contractile muscular ring at the end of the common duct when he found that a sound became obstructed at this level. Gage in 1879 first described a sphincteric apparatus in the cat, but it was in 1887 that Ruggieri (Oddi) gave the first exact and exhaustive description of a muscular ring in the dog, which he interpreted as an independent sphincter, finding the same formation in further research on other animals and man.

The concepts of Oddi were disputed in 1898 by Letulle and Nattan-Larrier, who denied the sphincteric ring. However the work of Mann in 1927 and of Chiodi in 1933 fully confirmed the conception of Oddi—that there was an independent sphincteric formation at the terminal portion of the common duct.

The sphincter of Oddi presents notable variations in various species of animals both as to development and intrinsic morphology. Morphologically the sphincter of Oddi may be considered as being constituted of two concentric muscular strata of different origin: an internal stratum which represents the fibromuscular tunic of the choledochus proper and a more external layer derived from the musculature of the duodenum. In certain animals like the dog the two are well differentiated, but in others like the ox, and likewise in man, there is an intimate fusion between the two. In man the sphincter of Oddi is represented by a robust muscular ring which surrounds the common duct before its penetration into the duodenal wall and accompanies it as far as the ampulla.

According to Hendrickson there are also longitudinal fibers which run parallel to the long axis of the common duct and extend to the papilla, by the contraction of these fibers a retraction of the ampulla is produced. This was confirmed by Helly in 1929. In 1931 Balli attributed an antagonistic action of these fibers to that of the circular fibers.

As to the physiology there is also much disagreement. Auster Crohn and Burget maintain that the duodenal musculature is the great factor and deny that the sphincter of Oddi is able by itself to act as an independent and sufficient sphincter. Coffey on the other hand maintains that it can.

The bile is secreted continuously by the liver and then intermittently excreted into the duodenum. It is logical to assume then that the gall bladder serves in a secondary capacity and that the tone of the sphincter of Oddi conditions the factors necessary for the filling and emptying of the gall bladder.

Experiment on animals show that fats and proteins relax the sphincter and drain bile, while carbohydrates seem to have no decisive action. Alkaline substances increase the pressure in the common duct while acid cause a relaxation as does magnesium sulfate (Meltzer and Lyon).

Oddi has demonstrated the existence of special nervous ganglia in the vicinity of the sphincter which were independent also as to morphologic characters from the intestinal plexus of Auerbach and Meissner.

The drug action on the sphincter is more or less accepted by all workers on the subject. Thus atropine relaxes the sphincter and causes a rapid fall in pressure in the common duct. Amylnitrate, trinitroglycerin and the pylline cause the same result but to a lesser degree. On the other hand morphine, colicine, pantoquine and dilaudid cause a spasm of the sphincter with increase in pressure. The drug action establishes the type of nerve supply to the sphincter. From these physiologic studies, contrary to the classic ideas of Donovan it results that the sympathetic nerves inhibit the tone of the smooth muscle of the choledochus and that the pneumogastric nerves reinforce it and their action is identical for the sphincter of Oddi.

The importance of the sphincter of Oddi in the process of bile was established by Meltzer and Westphal in 1923 and by Sakurai in 1927. These authors consider the last portion of the common duct to have two distinct portions: one part which runs behind it and through the wall of the duodenum called the "partio duodenalis" and a second part lower down with sphincteric action constituted by the muscular ring of the papilla of Vater, pilorus. When the sphincter is closed the partio duodenalis is relaxed and filled with bile and when the latter contracts the sphincter is relaxed and the bile is ejected into the duodenum.

A final and important function of the sphincter of Oddi is to prevent ascending infection as seen when cholecystogastrostomy or enterostomy is performed.

The authors next observed the repercussions in the mechanics of the biliary tree following the abolition

of the function of the sphincter of Oddi. Work along similar lines by Burget in 1920, Mallet-Guy, Auger and Croizat in 1933, Brendolon, Romeo, Bogetti, and Braco, and Colp and Doubilet is reviewed.

The authors then decided to proceed with experiments, using medium and large sized dogs. This animal was chosen because its sphincter is well developed. Four different types of procedures were followed. In the first, a simple section of the sphincter was performed through a longitudinal duodenotomy following a grooved sound as a guide. In the second type drainage of the common duct was done with a rigid tube of caudex according to the method of Stropeni. The tube was allowed to come through the lateral duodenal wall and then run along the mesenteric margin. This was fixed with sero-serous sutures in such a way as to obtain a tunnel in the duodenal wall. A new opening in the duodenal wall in the third portion then allowed the end of the tube to drain into the intestinal lumen. The length of the canal was 5 or 6 cm. In the third type suppression of the sphincter action associated with duodenal exclusion and gastroenterostomy was effected. The fourth type consisted of simple section of the sphincter and cholecystectomy.

Eighteen dogs, varying from 4 to 35 kgm. in weight, were used. Three died of varying causes and were excluded from the results. The remainder were sacrificed at varying intervals from several days to some months. A description of each dog and the results obtained are given as well as the postmortem radiologic, and histologic findings. The conclusions from these experiments are as follows:

1. Following the abolition of the sphincter of Oddi in dogs, a transitory dilatation of the extrahepatic biliary ducts develops. This is at its height on the fifth or sixth day and then progressively diminishes and finally disappears.

2. This dilatation is very similar to a nervous mechanism in its character and behavior.

3. The dilatation of the extrahepatic biliary ducts is always accompanied by an ascending enterogenous infection of mild degree which is limited to the extrahepatic tract and does not alter the hepatic function or general condition.

4. The association of cholecystectomy with abolition of the sphincter of Oddi impedes the dilatation of the extrahepatic ducts, a dilatation often found after simple cholecystectomy.

5. Following abolition of the sphincter of Oddi there are no findings which can definitely be interpreted as showing altered function of the biliary tree, nor do they show an involution of the gall bladder.

LOUIS J. FROWDE, M.D.

Carcinoma Involving the Common Bile Duct. II. E. LESTER. *Surgery* 1947 36:7

Cancer of the common bile duct produces symptoms early and supposedly develops metastases late. Despite this, most patients eventually die of recurrent cancer and those who do not die of the cancer succumb to repeated attacks of cholangitis. The

avoidance of ascending liver infection which so commonly follows plastic procedures and reimplantation of the common bile duct is a major problem that is not yet solved.

The author presents 4 cases in which resection of the choledochus was performed for carcinoma. In 3 of these segmental resection was done and in 1, a one-stage duodenopancreatectomy was done. Both of the segmentally resected patients died 9 months following operation with symptoms of cholangitis, those with duodenopancreatectomy survived 19 months and 7 months, respectively, both had symptoms of metastasis and cholangitis. Autopsies were not performed.

FRANK B. QUINCY, M.D.

Contributions to the Knowledge of Pancreatic Reflux as an Etiologic Factor in Chronic Affections of the Gall Bladder. An Experimental Study. EARL H. JOHNS. *Acta chir.* 1946 94:7 66, Supp. 34

The original suggestion for this investigation occurred a few years ago in connection with an abdominal operation for an acute condition in a patient who presented clinical symptoms of peritonitis. At operation, 300 ml. of bile-colored fluid were found within the peritoneal cavity, evidently emanating from the greatly distended, edematous, and cyanotic gall bladder the wall of which was moderately thickened. No macroscopically observable perforations of the gall bladder or of the extrahepatic bile ducts were recognized. In addition to several hundred calculi, the gall bladder contained dark, slightly cloudy bile which on bacteriologic examination proved to be sterile. This fact in conjunction with the digested appearance of the gall bladder suggested the possibility of a pancreatic ferment as the cause of the disease. In all probability this was a relatively rare disease which in the literature, is termed nonperforative bile peritonitis. Clinical observations and experimental studies have shown that the disease is caused by a reflux of pancreatic juice to the gall bladder. It seemed obvious therefore, that pancreatic ferment may be a possible etiologic factor also in chronic affections of the gall bladder.

The stereotyped pathologic-anatomic pictures in chronic cholecystitis and the fact that in this disease the gall bladder bile often is sterile, are the 2 phenomena which suggested that a pancreatic ferment may be the cause of chronic cholecystitis. With regard to the formation of calculi, it was established long ago through studies on the morphology of the gall stones, that the center of the gall stones often consist of a nucleus made up of more or less necrotic epithelial cells, mucus and bacilli. The origin of these cells may be traced to the gall bladder epithelium which has been subjected to the desquamative proteolytic process described by Martensson (1941) and considered to be the initial stage in the formation of calculi. It is quite obvious that, among the pancreatic fermenta the trypsin (activated) must be the enzyme which would cause this change as well as other possible changes in the gall bladder wall.

efflux of pancreatic juice to the bile ducts can be cause of chronic diseases of the gall bladder only in as far as this process relatively often is rendered possible by the conditions of the openings of the pancreatic duct. The objective of the author was study of the anatomic communication facilities reflux of pancreatic juice in man, based on a pathologiccoanatomic investigation.

An investigation on the presence of pancreatic contents in the gall bladder bile in man in connection with cholecystectomy has been carried out in an attempt to prove that reflux of pancreatic juice actually occurs. Further an investigation was made in animals in order to ascertain whether and in what extent, trypsin causes pathologiccoanatomic changes in the gall bladder wall and possibly the formation of calculi.

Reflux of pancreatic juice can on the whole occur on condition that the anatomic relationship between the pancreatic and the bile duct renders it possible. A brief survey is given of the very convincing results obtained by various investigators with regard to the relationship between the bile and the pancreatic duct. Also an account is given of a pathologiccoanatomic study by the author on the openings of the ducts in man. The method applied is discussed. One hundred patients (50 men and 50 women) were examined and cholangiographic studies of 430 patients were made with regard to the visualization of the pancreatic duct. On the basis of the results achieved the following conclusions are drawn: (1) possibility of anatomic communication between the pancreatic and common duct exists in 86 ± 3 per cent. (2) visualization of the pancreatic duct by means of cholangiography occurs in 46 ± 4 per cent, which must be regarded as a minimum figure, the reasons for which are stated. (3) Santorini's duct in open communication with the duodenum occurs in men in 44 ± 7 per cent and in women in 14 ± 9 per cent, the difference of 30 ± 8 per cent is significant and has not been observed previously. The explanation of the preponderance of biliary affections in women may be sought in this anatomic difference between the sexes.

Previous investigations on the presence of pancreatic ferments in the bile ducts in man are surveyed. The author's material includes 100 chronic cystectomized gall bladders, the contents of which have been examined for diastase according to Norby's method. 15 of these gall bladders show from 0.06 to 11 activity units of diastase per milliliter of bile. The derivation of this ferment is discussed with regard to cells and bacilli occurring in the bile, the liver as a possible source, secretion of diastase via the blood or lymph passages, and inflow of duodenal juice through the duodenal papilla, all of which have been considered improbable sources. The author infers that the recognized ferment must originate from the pancreas through reflux. This theory is supported by the fact that the pancreatic duct was visualized in 6 out of the 9 patients examined by means of cholangiography.

In view of the stereotyped pathologiccoanatomic pictures in chronic cholecystitis and the fact that in this disease the gall-bladder bile as well as the gall bladder wall are remarkably often sterile the author has presumed that the pancreatic trypsin would be the causative factor. Morphologic studies of gall stones have revealed that they contain a central nucleus consisting of necrotic cells, mucin and bacilli. It may be presumed that lesions on the gall bladder epithelium caused by trypsin are the origin of these cells.

Previous experimental investigations on lesions of the bile ducts caused by pancreatic ferments are also surveyed. These are chiefly concerned with acute lesions. The author reports the results of his experimental study on chronic affections of the gall bladder caused by trypsin. 31 rabbits were used, 10 of them as control animals, and the method is described. Of the 21 animals in which trypsin was injected into the gall bladder 20 presented more or less advanced pathologiccoanatomic changes in the gall bladder manifested by chronic cholecystitis. These changes are similar to the changes occurring in chronic cholecystitis in man. Ten experimental animals also presented firm concretions. The control animals in which inactivated trypsin was injected into the gall bladder but which were otherwise subjected to exactly the same treatment as the experimental animals presented no remarkable changes in the gall bladder wall, with the exception of pathologiccoanatomic pictures of very mild chronic cholecystitis in 2 instances. On the basis of the result of the experiment the author makes the following inference:

1. Active trypsin injected into the gall bladder of a rabbit with simultaneous occlusion of the cystic duct will after 5 weeks to 13 months produce pathologiccoanatomic pictures of more or less pronounced chronic cholecystitis.

2. These changes in the gall bladder are associated with the formation of calculi in some instances.

3. Inactivated trypsin injected into the gall bladder of a rabbit under similar experimental conditions causes no remarkable pathologiccoanatomic changes in the wall.

4. The diagnosed pathologiccoanatomic changes in the gall bladder reproduce very strikingly the different stages of those pathologiccoanatomic changes which occur in the so-called chronic stone gall bladder in man.

5. That the chemical structure of the experimentally produced calculi does not completely conform to that of gallstones in man must be considered to be of secondary importance in comparison to the general recognition of such bodies, especially as spontaneously developed biliary calculi were never diagnosed in the experimental animal used and therefore it must be presumed that this animal lacks the capacity for the formation of biliary calculi, a condition which may perhaps be explained by the fact that the pancreatic and common ducts open separately in this animal.

Physioclinal aspects of pancreatic reflux conclude the study
BENJAMIN GOLDMAN, M.D.

Chronic Recurrent Pancreatitis: A Clinical Study of 20 Cases. SAMUEL N. MARMON, JOSEPH B. KIRSNER, and WALTER LINCOLN PALMER. *Arch. Int. Med.* 1948, 81, 56

Because the entity chronic pancreatitis is seldom considered clinically, the authors have reviewed the significant manifestations as observed in 20 cases.

Bouts of severe pain in the upper abdomen are the most frequent and outstanding complaint. The importance of considering the possibility of pancreatitis in the treatment of patients with pain in the upper part of the abdomen following operation on the biliary tract is evident, and careful exploration of the pancreas is emphasized especially when laparotomy done for signs of biliary colic, fails to disclose gall stones. The difficult differentiation between benign and neoplastic lesions is discussed.

For aid in establishing the diagnosis of chronic pancreatitis the following facts are tabulated:

The physical findings are indefinite and jaundice may occur in the absence of calculi; the biliary tract when pancreatitis is present. Among 8 cases in which the serum amylase was determined it was found elevated in 3 of them, normal in 4, and decreased in 1. The oral glucose tolerance curve which shows a diabetic type of curve is of help in the diagnosis. Pancreatic calcifications are a frequent roentgenological finding. Disturbance of carbohydrate metabolism was frequent and steatorrhea not uncommon in this series.

The fact that half of the patients in the series had had previous surgical treatment for the biliary tract suggests that pancreatitis must be considered in patients with continued pain following cholecystectomy.

In summarizing their surgical results the authors state that surgical intervention gives good results in patients with obstruction of the common duct and in those with constriction of the duodenum. Removal of ductal calculi frequently relieves pain, while steatorrhea may be favorably affected. An established diabetic state tends to remain unaltered.

W. FOSTER MONTGOMERY, M.D.

Carcinoma of the Gall Bladder. FRANK P. SARKIS and JOHN H. GARLOCK. *Surgery* 1948, 3, 50

The authors believe that cancer of the gall bladder is not of infrequent occurrence; some published reports to the contrary notwithstanding. Between the years of 1933 to 1946 inclusive there were encountered 75 individuals with cancer of the gall bladder at the Mount Sinai Hospital, New York. The diagnosis was verified histologically in 65 patients after operation and in the remaining 10 at necropsy (5 of the latter 10 individuals were moribund on admission to the hospital while the remaining 5 died of unrelated disease). Of the 65 patients who underwent surgery only one patient was alive over 13 years following operation for supposed chol-

ecystitis, death of the remaining 64 patients occurred within 35 months after operation.

The sex incidence showed a ratio of 5.2 women to 1 man. The cardinal symptoms were abdominal pain especially in the right upper quadrant, in 77.3 per cent; loss of weight in 41 per cent; jaundice in 38.6 per cent; and a palpable mass in the upper quadrant of the abdomen in 64 per cent. The pathologic observations at operation varied from a picture suggestive of cholecystitis to a totally inoperable new growth involving many abdominal organs in some cases. In 7 patients in whom cholecystectomy was performed for suspected cholecystitis, the pathologist reported unsuspected carcinomas.

The histologic diagnoses were as follows: adenocarcinoma (82.7 per cent), squamous cell carcinoma (4 per cent) and unspecified carcinoma (13.3 per cent). Concomitant cholelithiasis was encountered either at operation or at autopsy in 73.3 per cent of the patients. Reformed stones were found in association with carcinoma in 3 cases following an antecedent cholecystectomy. The high incidence of association of cholelithiasis with carcinoma suggests that stones may be a precursor of carcinoma of the gall bladder. This assumption is supported by clinical (Graham, Kirschbaum, and Kosoff, Warren and Balch and Finney and Johnson) and experimental (Kasama and Leitch and Petrov and Krothman) studies. That the reverse is not probable, that is, that stones are not produced by the malignant process, was pointed out by Graham who found an incidence of only 8 per cent of stones in metastatic carcinoma of the gall bladder.

Sainburg and Garlock believe that cholecystectomy for silent or symptomatic cholelithiasis is a sound prophylactic measure against the occurrence of neoplastic transformation which when diagnosed clinically is virtually an incurable disease.

Splenic Tissue in the Scrotum. ERLAND SARTOR. *Acta chir. scand.*, 1948, 96, 388.

The author reports the case of a patient with ectopic splenic tissue in the left half of the scrotum. He cites earlier publications (5 cases) and discusses the genesis of this anomaly. In the differential diagnosis of tumors located in the left half of the scrotum, the possible existence of such accessory splenic tissue should be borne in mind.

Syndrome of an Acute Condition of the Abdomen Caused by Spontaneous Extraperitoneal Rupture of the Retroperitoneal Blood Vessels (Les syndromes abdominaux aigus par rupture spontanée sous-péritonéale des vaisseaux rétro-péritonéaux.) J. LASSERRE. *Rev. chir. P.* 1947, 66, 246, 282, 368.

The author discusses 16 cases collected from the literature in which the rupture of a retroperitoneal vessel produced the clinical picture of an acute con-

of the abdomen. Except in 3 cases of arterio- of the aorta, the hemorrhage was caused by of an aneurysm either of the abdominal (11 cases) or of the common iliac artery (3). It should be mentioned that in none of the 16 the correct diagnosis of this rare condition was made prior to surgery or autopsy.

The attack begins quite suddenly with excruciating pains in the lower abdomen and signs of shock, followed by syncope. The pains irradiate into lumbar and gluteal regions and along the thighs. In rare cases only was it possible to palpate the mass as a diffuse mass, more often on the left on the right side. Even rarer were the cases in which it was possible to palpate the aneurysm itself as a pulsating mass with well defined borders close to the hematoma.

In 3 cases only an x ray examination was made which revealed an opacity with indistinct borders in the left flank which blurred the shadow of the kidney and the psoas muscle. Three cases simulated the picture of acute peritonitis and the patients underwent surgery with the diagnosis of ruptured appendix or volvulus. In 2 other cases ecchymoses into the scrotum and the root of the penis were observed several days after the attack, the hematoma having spread through the inguinal canal to the genital region. In most cases the patients died within hours or a few days after the attack. In those who survived the initial attack, the picture of a paralytic ileus developed several days later and led to exploratory laparotomy in several instances.

The outcome has been fatal in all cases. Ligature of the ruptured artery or aneurysm was not tried in any instance. WALTER M. SOLMITS, M.D.

Gastric Syphilis in Pseudoneoplastic Form (*La syphilis gastrique a forme pseudoneoplasique*). PAUL CHENE, MME. PILLET-SAVATON and ANDRÉ SIMON. *Presse med.* 1947 No 74 874.

Roentgenologically a 56 year old woman exhibited shadow defects of the greater curvature of the antrum suggesting neoplasm while anorexia, vomiting and regurgitation had led to extreme emaciation, abdominal ascites, and pronounced enlargement of the liver and spleen. Later megasophagus was noted. The patient refused treatment by surgery and later developed jaundice and finally a gumma of the frontal region. Under vigorous antisyphilitic treatment the roentgenologic findings in the stomach and cardia and the ascites disappeared, however some enlargement of the spleen and macronodular liver persisted.

The authors ascribe the antral phenomena to a syphilitic perihepatitis and the cardiac symptoms to a syphilitic perisplenitis; that is they believe that the entire process was the result of a syphilitic perivisceritis and think that such a process may be in effect in many other disease pictures.

This condition is compared with the so-called *mal de Engasgo* of the Brazilian doctors who describe this endemic esophageal dilatation in the regions of Brazil which are infested with malaria (paludal perisplenitis). JOHN W. BRENNAN, M.D.

UTERUS

Contribution to the Morphological Study of the Ovary and of the Endometrium in Myofibromas of the Uterus (Contributo allo studio morfologico dell'ovario dell'endometrio nei miofibromi uterini) EARENTO MORACCI. *Arch. ital. clin.* 1947 53 193

After stating the different views regarding the clinical coexistence of myofibroma, polycystic ovary and glandular hyperplasia of the endometrium, the author found such a divergence of ideas that he was prompted to study the material of 20 cases of myofibromas subjected to subtotal hysterectomy and bilateral adnexectomy to ascertain in each case the morphologic characteristics of the ovary and endometrium in order to deduct functional characteristics and the possible clinical manifestations.

The findings of the morphologic study of the ovary and endometrium in the 20 cases of uterine myofibromas were as follows:

1. A polycystic ovary was found in 17 cases, but in only 3 cases was there a concomitant glandular cystic hyperplasia of the endometrium (considered to be certain anatomical evidence of hyperandrogenism). Eleven cases presented simple glandular hyperplasia, and 4, normal uterine mucosa in different functional stages.

2. In 3 cases, a sclerotic ovary with diffuse follicular atresia was found and the uterine mucosa presented an atrophic aspect.

3. In 11 cases active corpora lutea were found in the ovaries. The remaining cases had only corpora albicantia.

4. In the cases of simple glandular hyperplasia the endometrium revealed concomitant zones of thrombosis and necrosis of the vascular walls.

5. In 18 cases the author ascertained the presence of menorrhagia, metrorrhagia and a condition bordering on metrorrhagia. The bemic losses seemed to be associated with hyperplastic as well as atrophic changes of the uterine mucosa.

6. Although it can be admitted that uterine fibromyomas are usually accompanied by a dysfunction of the ovary there are no favorable data to indicate that the genesis of the tumor is always related to hyperproduction of estrogenic hormone.

JOSEPH M. A. PATE, M.D.

The Use of Multiple Sources of Radium Within the Uterus in the Treatment of Endometrial Cancer. A. N. ARMSTRONG, WILLIAM W. STANBRO, and JAMES F. NOLAN. *Am. J. Obst.* 1948, 53 64.

A total of 93 patients were treated for corpus cancer at the Barnes Hospital and the Barnard Free Skin and Cancer Hospital, St. Louis, Missouri from 1936 to 1941 inclusive. The method of radium treatment was changed from one employing intrauterine tandems to a technique using multiple cap-

sules of radium packed individually into the uterine cavity in the attempt to fill all the available space. The use of radium was preceded by the external application of x-rays. The period of years included in the report antedates the onset of the planned method of treatment established in 1938.

The attempt is made to compare the relative effectiveness of treatment with intrauterine tandem of radium, and by the use of multiple capsules. For that comparison the effect of certain biologic properties of tumor growth are also considered in their relation to the end results.

Variation in survival rate is found with histologic type, for treatment by radiation alone as well as in conjunction with hysterectomy. Better results were obtained in the more highly differentiated forms. An improvement in clinical results was obtained with the use of multiple capsules.

Variation in survival rate is found also with size of the uterus. For treatment by radiation alone the results in uteri of small size were about equal for tandems and multiple capsules. In these cases a linear arrangement of radium tubes may fill the uterine cavity with reasonable completeness. Among 4 patients with large uteri, however, there were no 5 year survivors following treatment with x-rays and radium tandem alone. The use of intrauterine tandems in conjunction with surgery resulted in survival of about half of the patients. Only 3 showed enlargement of the uterus. The results from the use of multiple capsules and hysterectomy appear essentially independent of uterine size. About three-fourths of each group survived the 5 year period.

Despite the fact that the survival rates were affected by both histologic type and uterine size, improvement in the clinical results could be shown by the use of multiple capsules when comparison was made on the basis of radium treatment only. Among patients treated by radiation alone the use of intrauterine tandems resulted in survival of only 33 per cent, but 53 per cent of those irradiated with multiple capsules were alive and well at the end of the 5 year period. For treatment by irradiation and hysterectomy the use of intrauterine tandems resulted in survival of 54 per cent, but survival following the use of multiple capsules of radium was 79 per cent.

More reliable than histologic type or uterine size in establishing the clinical result to be expected was the persistence or disappearance of tumor within the uterus after preoperative irradiation. Among 32 patients treated by hysterectomy after the use of x-rays and radium, a persistent tumor was identified in 47 per cent of which group only 46 per cent survived for a 5 year period. Among the patients in whom no tumor was identified the survival rate was 83 per cent. Persistent tumor was found in 77 per cent of the patients irradiated by tandems. Only 26 per cent of those in whom multiple capsules were

employed showed viable cancer in the specimen removed at hysterectomy.

A discussion is given upon the improvement in distribution of radiation and in tissue dose for sources of radium within the uterus. By means of this method it has been practical to increase the total amounts of radiation employed without the accidental sequelae in 2 patients are described and the interval between preoperative irradiation and hysterectomy is discussed. JOHN R. WOLFF, M.D.

Treatment of Cervical Cancer LUDWIG ADLER. *Acta radiol. Stockh.* 1947 28 474

The author presents a survey of the history of surgery and radiotherapy in the treatment of cancer of the cervix, and describes his elective treatment of the disease (extended vaginal operation with immediate postoperative insertion of radium in most cases) which he has used for more than 20 years. A paratomy with radium insertion is performed in patients unfit for vaginal operation. Inoperable cancers and bad surgical risks are irradiated only.

The permanent cures following the elective treatment amounted to 39.4 per cent. Within the last 15 years the primary mortality was 3.9 per cent. Attention is called to the morbidity accompanying irradiation.

DANIEL G. MORTON, M.D.

Summary of Results in the Radiation Treatment of Uterine Cervical Cancer HAROLD SWANBERG. *Acta radiol. Stockh.* 1947 28 554

The author presents a statistical study of 1,796 patients who suffered all stages of cancer of the uterus in the cervix and who were treated exclusively by radiation therapy in 18 well known radiotherapeutic centers in 8 countries. Treatment was begun in 1933. The analysis of the end results was made 5 years later.

The conclusion is reached that of all 18 radiotherapeutic centers, regardless of the number of patients treated, the best results were secured at the Radium Institute of the University of Paris where 47.2 per cent of all patients treated were alive and free from cancer at the end of the 5 year period.

The radiation technique which was used in Paris to secure these results consisted of combined internal (intracavitary) and external (transpelvic) irradiation (internal radium alone in stage 1); the internal radium treatment consisted of multiple small milligram centers of heavily filtered radium distributed through out the entire length of the uterine canal and the width of the vaginal vault. The radium was administered slowly over a period of 5 days time and patients received an average of 8,000 milligram hours of treatment.

ADNEXAL AND PERIUTERINE CONDITIONS

Clinical and Pathologic Survey of Ovarian Tumors Treated at Radiumhemmet; Dysgerminomas. LARS SANTESSON. *Acta radiol. Stockh.* 1947 28 644.

The author presents the first part of a clinical and pathological survey of about 700 cases of ovarian

tumors treated at Radiumhemmet through 1940. Among these there were 26 cases of dysgerminoma which the author reviews together with 11 cases of dysgerminoma 10 patients who were treated in later years. In addition 192 cases from the literature are reviewed. Only those cases are included which in all respects show histological structures typical of this rather rare type of ovarian tumor. The incidence of pure dysgerminomas in the whole material of ovarian tumors at Radiumhemmet is 3.7 per cent. Five year results are available for 27 of the 37 cases of dysgerminoma at the Radiumhemmet.

It should be remembered that Radiumhemmet is a clinic which is operated principally for the radiological treatment of tumors. For this reason only those patients who might benefit by such treatment are admitted. The material collected there must thus be of a specially selected type and not representative of material found in clinics designed for treatment of general surgical conditions.

The clinical symptomatology of dysgerminomas is generally not distinctive and corresponds largely to that of other solid ovarian tumors. The duration of symptoms in this series as in the cases described earlier was short which suggested a rapid tumor growth.

Meyer in 1925 laid stress upon the frequent occurrence of dysgerminoma with pseudohermaphroditism, hypogonadism and other forms of sexual maldevelopment. In this material however only 5 cases showed such maldevelopment and in 129 cases (of 187) collected from the literature the tumor occurred in an otherwise normal person.

The dysgerminoma predominantly affects young individuals under 30 years of age. In 28 of the cases in this series the tumor occurred in patients under 30 years of age.

The malignancy of the dysgerminomas appears partly through local infiltration of the surrounding tissues and partly by giving rise to metastases. The infiltration occurs especially along the intraligamentary lymphways. The capsule is only rarely broken through but large tumors may rupture and in this way produce peritoneal implantation metastases. Rupture may occur either spontaneously or at operation, and is of serious consequence. Rupture occurred before operation in 6 of the patients who had been treated more than 2 1/2 years previously. Five of them have died although in 2 the operation was considered radical. Peritoneal implantation metastases were found at operation in the other 3 patients.

Usually, these tumors metastasize along the lymphatics first to the retroperitoneal lymph nodes along the large abdominal vessels, later to the mediastinal lymph nodes. From there they may disseminate through the thoracic duct to the supraclavicular region. Hematogenic dissemination may occur but is rare. Occasionally a positive Aschheim-Zondek reaction is present.

If these cases are counted together with the cases in the literature in which the location is mentioned

ADNEXAL AND PERIUTERINE CONDITIONS

Clinical and Pathologic Survey of Ovarian Tumors Treated at Radiumhemmet; Dysgerminomas.
LARS SAMTERSON *Acta radiol., Stockh. 1947 18 644.*

The author presents the first part of a clinical and pathological survey of about 700 cases of ovarian

tumors treated at Radiumhemmet through 1940. Among these there were 26 cases of dysgerminoma which the author reviews together with 11 cases of dysgerminoma in patients who were treated in later years. In addition 192 cases from the literature are reviewed. Only those cases are included which in all respects show histological structures typical of this rather rare type of ovarian tumor. The incidence of pure dysgerminomas is the whole material of ovarian tumors at Radiumhemmet is 3.7 per cent. Five year results are available for 27 of the 37 cases of dysgerminoma at the Radiumhemmet.

It should be remembered that Radiumhemmet is a clinic which is operated principally for the radiological treatment of tumors. For this reason only those patients who might benefit by such treatment are admitted. The material collected there must thus be of a specially selected type and not representative of material found in clinics designed for treatment of general surgical conditions.

The local symptomatology of dysgerminomas is generally not distinctive and corresponds largely to that of other solid ovarian tumors. The duration of symptoms in this series, as in the cases described earlier, was short which suggested a rapid tumor growth.

Meyer in 1925 laid stress upon the frequent occurrence of dysgerminoma with pseudohermaphroditism, hypogonadism and other forms of sexual maldevelopment. In this material however only 2 cases showed such maldevelopment and in 129 cases (of 187) collected from the literature the tumor occurred in an otherwise normal person.

The dysgerminoma predominantly affects young individuals under 30 years of age. In 28 of the cases in this series the tumor occurred in patients under 30 years of age.

The malignancy of the dysgerminomas appears partly through local infiltration of the surrounding tissues and partly by giving rise to metastases. The infiltration occurs especially along the intraligamentary lymphways. The capsule is only rarely broken through but large tumors may rupture and in this way produce peritoneal implantation metastases. Rupture may occur either spontaneously or at operation and is of serious consequence. Rupture occurred before operation in 6 of the patients who had been treated more than 2½ years previously. Five of them have died although in 2 the operation was considered radical. Peritoneal implantation metastases were found at operation in the other 3 patients.

Usually these tumors metastasize along the lymphatics first to the retroperitoneal lymph nodes along the large abdominal vessels later to the mediastinal lymph nodes. From there they may disseminate through the thoracic duct to the supraclavicular region. Hematogenic dissemination may occur but is rare. Occasionally a positive Aschheim-Zondek reaction is present.

If these cases are counted together with the cases in the literature in which the location is mentioned

the tumors were located in the right ovary in 51 per cent of the patients in the left ovary in 30 per cent and bilaterally in 17 per cent.

Macroscopically these tumors are rounded, with smooth or coarsely lobulated surfaces, and are enclosed in fibrous capsules that remain intact in the early stages, but sometimes rupture in advanced stages. The consistency varies from hard and rubbery in the smaller tumors to spongy and friable in the larger ones. On cut surface, the tumor appears to be of a grayish-pink color often with areas of a distinctly yellowish hue. The tumor mass is rather homogeneous. Strands of fibrous tissue may however, divide it into lobules.

There are few tumors of the ovary which present such distinctive characteristics as does the dysgerminoma. This applies to both the cell type and the general architecture.

The dysgerminoma cells are markedly uniform rather large, round, or polyhedral and have a moderate amount of granular or clear, often translucent cytoplasm containing relatively large amounts of glycogen. The nuclei are large, vesicular with thick nuclear membranes. They are rich in chromatin and have usually more than one well developed highly basophilic nucleolus. Mitotic figures are present in varying, often large, numbers. The structure of the cells is suggestive of cells in rapid proliferation. The arrangement of the tumor cells is rather characteristic, although it varies even in different parts of the same tumor. The cells are arranged either in single-layered columns or in strands, in small acini-like groups or in larger irregular nests of cells, separated by a more or less abundant and usually delicate network of connective tissue stroma. A most prominent feature is that the stroma is abundantly infiltrated with lymphocytes which sometimes even form actual lymph follicles with a distinct germinal center.

Regressive changes are frequent and often so extensive as to constitute another specific feature of the tumor. They consist in a progressive acidophilic necrobiosis with fatty degeneration or intracellular calcification and finally necrosis.

The histological structure of dysgerminoma is undoubtedly that of a malignant tumor. The authors have not been able to correlate the degree of malignancy with any particular microscopic feature.

There seems to be general agreement that the prognosis must be considered as serious, although not as bad as in cases of histologically clearly malignant ovarian carcinomas. The number of cases in the literature which have been followed over 5 years is, however still rather small. Thus, of the 98 cases studied by Seegar in 1938 there are only 40 cases in which the 5 year results can be studied, and among 102 cases assembled from the literature by the author there are only 80 such cases.

As has already been pointed out, it has not been found possible to judge the prognosis from the histological structure of the tumor. It seems, on the other hand that rather reliable prognostic judgment can

be based on the extension of the tumor process observed at operation. Of 61 patients in whom the tumors were still confined to the ovary and with intact capsule (39 from the literature and 22 from this material) 49 patients are living over 5 years and the rest have died as a result of the tumor while of 28 patients (21 from the literature and 7 from this material) in whom there was evidence of a break in the capsule 24 have died from the tumor and only 4 are living over 5 years.

The survival rate in all of the 5 year cases is 51 per cent (55 of 107 cases). Of the patients treated at Radiumhemmet more than 5 years ago this rate is 66.7 per cent (18 of 27 cases).

There seems to be a general agreement that radical surgical removal of the tumor, followed by radiotherapy is the treatment of choice for dysgerminomas. There are, however different opinions as regards the necessary extensiveness of the operation as well as of the radiological treatment. A detailed attempt is made to judge the value of radical versus conservative surgery and of deep x-ray therapy. The number of cases is still too small to allow any definite judgment of the risks as compared with the gains entailed in the conservative mode of surgical procedure, which is warranted only if it is followed by radical radiological treatment, i.e. prophylactic radiation directed at the unaffected ovary. The author further states that "radical prophylactic radiological treatment given in the right manner does not impair the functions of the unaffected ovary left at the operation. Thus, in such cases the menstruations mostly return and even pregnancies with the birth of normal children may occur."

Five fields of roentgen treatment have been used— one abdominal field, one on the back against the pelvic region on each side, and one central field against the upper part of the back up to the diaphragm. This last field is of special importance in the prophylactic roentgen treatment because of the fact that these tumors at first mostly metastasize to the retroperitoneal lymph nodes along the large abdominal vessels. The doses have varied from 400 to 600 roentgen units given in separate treatments of from 100 to 300 roentgen units with 0.5 mm. of copper as filter. On the field over the upper part of the back the doses have been somewhat smaller.

Among the cases assembled from the literature, there are only 3 cases of patients operated upon and radiologically treated for whom 5 year results are given. Twelve of these have lived over 5 years, a survival rate of 57.1 per cent. If these cases are counted together with the cases in this material, the survival rate is 62.5 per cent (30 of 48 patients). There are, on the other hand 48 cases in the literature with 5 year follow-up data. These patients according to the given clinical histories, have only been operated upon and have not been radiologically treated. Of these 48 patients, 20 (41.7%) have lived over 5 years. These figures indicate how important the radiological treatment is in obtaining the best results in patients with dysgerminomas.

Editorial comment: There are few radiologists in this country who would regard the doses given as can-
cridal, furthermore the persistence of normal
activity in the remaining ovary in spite of radio-
logical treatment would seem to indicate that
counts given were insignificant.

MISCELLANEOUS

Multiple Blastomatosi and Preblastomatosi of the Genital Tract with Particular Attention to the Endocrine Oncogenetic Factors (In tema di blastomatosi multiple e di preblastomatosi della sfera genitale con particolare riguardo ai fattori oncogenetici endocrini). GIUSEPPE NIOSI, CORRADO Ginecologia, Tor. 1947 13 453.

A woman 57 years of age, who had had 3 normal pregnancies and had entered the menopause without disturbances 5 years previously, reported moderate loss of blood from the genitalia for the past 4 months. Gynecologic examination disclosed only that the uterus was slightly larger than normal. Curettage was performed and the histologic diagnosis was hyperplasia and glandular hyperplasia of the endometrium. She was given 6 castration doses of roentgen rays. About 5 months later she was re-admitted to the hospital with a history of another blood loss of 15 days' duration, followed by rapid and progressive enlargement of the abdomen which contained a round tumefaction the size of a 7 months' pregnancy. At operation a large tumor of the left ovary was removed. The histologic diagnosis was proliferating adenocarcinoma with signs of malignancy. After 5½ months she was again admitted because of irregular blood losses for a period of 3 months; she was treated by curettage. The histologic diagnosis was adenocarcinoma of the endometrium. The uterus and the right ovary were then removed.

There is no doubt that the ovarian tumor was present before the metrorrhagias occurred; that the latter were due to the former; that the uterine carcinoma was not yet present at the time of the first metrorrhagias and was not a metastasis from the ovarian tumor. The two tumors must be regarded as independent and possibly the expression of a special state of predisposition (oncogenous diathesis) of woman to tumors in general and to those of the genital tract in particular.

To interpret the succession of morbid elements in the present case it is necessary to consider the question of the genesis of the blastomas. Many authors

have already stated that there must be a connection between internal secretions and the genesis of the tumors, and the literature on the subject has assigned an important rôle in this to folliculin in particular, but the mechanism by which folliculin causes this cellular disturbance is still unknown. It is practically certain that there is a preblastomatous stage which may extend itself into the true blastomatous stage, i.e., the same stimuli which are capable of inducing in a normal tissue such structural and functional changes as to make it resemble a neoplastic tissue are also apt to cause the formation of real neoplasms. There is no doubt that the morbid forms known as cystic glandular hyperplasias of the endometrium belong to the preblastomatous stage and it is logical to suppose that uterine or internal adenomyosis may also be part of this stage. Therefore the simultaneous and successive presence of precancerous and cancerous stages is illustrated in this patient (ovarian tumor in its initial stage and hyperplasia of the endometrium).

Could not the two lesions be the result of the same factor which acting simultaneously on different organs encounters a different reaction and resistance in the ovary and in the uterus so that the response is the formation of a tumor in the first, but is limited to the preneoplastic stage in the second? The persistence of the stimulus acting on the endometrium could then lead to ulterior evolution of the mucosa so that the preblastomatous proliferation passes into the true blastomatous stage. In fact the second curettage revealed adenocarcinoma of the uterus.

In menopausal women there is a discharge in the circulation of prolactin A, which may reach considerable quantities. The relations between this hormone and folliculin are well known. An eventual impulse to the production of folliculin may become more or less continuous and be of more or less marked degree; therefore rather large quantities of folliculin may be poured into the circulation either continuously or more probably intermittently. The author thinks that such an eventuality occurred in his patient who presented a succession of preneoplastic and neoplastic manifestations. It is possible that if the first intervention had been more radical and had included also removal of the apparently normal opposite ovary the adenocarcinoma of the uterus would not have appeared. This fact should be kept in mind to serve as a guide in the operative conduct of the gynecologist in similar cases as it would eliminate another source of folliculin.

RICHARD KEMEL, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

A New Biologic Reaction for the Diagnosis of Pregnancy G. M. Mainini's Reaction (Una nueva reacción biológica para el diagnóstico precoz de la gestación. La reacción de Galli Mainini) ALFONSO POY D. SANTIAGO. *Arch. Surg. med.* 1947 307 457

The author discusses the various classic tests for pregnancy. An appraisal of each is given. Besides being time-consuming each has some drawback in procedure which makes the test impractical for immediate diagnosis. He describes the Galli Mainini test and recommends it because it is accurate (from 97 to 98%) is time element is negligible ($\frac{1}{2}$ to 4 hours), it is cheap (the common male toad found everywhere in Uruguay is used), and it is simple (it can be done by any technician in any laboratory).

The test consists in the injection of 10 c.c. of urine of the woman suspected of being pregnant into the lateral lymphatic sac of the toad (*Bufo-arenarum* Henae). One half-hour later the toad's urine is collected from the cloaca by means of a special glass catheter and is examined microscopically. If there is a pregnancy spermatozoa appear in large quantities as so many small commas moving rapidly through the fluid.

STEPHEN A. ZIEGLER, M.D.

Blood Volume in Pregnancy CHARLES E. McLENNAN and L. G. THORNTON. *Am. J. Obst.* 94:5, 55-59.

Despite the fairly general acceptance of the theory that there is a real increase in volume of plasma and red cells during pregnancy, there is no agreement as to the precise magnitude of this increase at the various stages of gestation or the rapidity with which the volumes return to normal in the postpartum period.

The authors present a chromatographic technique for the extraction of Evans blue from plasma to determine the plasma volume and from this value the total blood volume is calculated by use of the hematocrit. Determinations were made on 20 normally pregnant women at term and on the same women 7 days after delivery. A control group of 10 normal nonpregnant women was used to check the results with this technique against previously determined standards for normal females.

At term the average value for plasma volume was about 40 per cent greater than plasma volume in the control series and the total blood volume was 32 per cent greater. While the red cell volume appeared to rise about 20 per cent, the significance of this change was not so striking as in the case of the plasma volume and the total blood volume. Within a week after delivery the blood volume had returned virtually to nonpregnant levels.

Individual variation in the blood volume during pregnancy is enormous. Standard deviations are

relatively much greater for pregnant subjects than for either the controls or postpartum patients.

A few observations indicate that the dye-dilution method is not invalidated by transfer of the dye across the placental barrier but the question as to whether dye is trapped at the placental site is still unsettled.

Data from several previous publications has been subjected to statistical analysis and certain unwarranted conclusions previously made have been critically reviewed.

The authors of previous articles on blood volume in pregnancy have speculated freely on the cause or causes of the apparent increase in volume. The recent finding of Furth and Sobel that granulosa cell tumors in mice were associated with hypervolemia revives the suggestion that increased estrogen levels are in some way concerned with elevation of the blood volume.

The authors conclude that it seems unlikely that anything yet published, including this report, has given a thoroughly reliable picture of what happens to the blood volume in pregnancy. A great many more determinations should be made and the validity of dye techniques must be ascertained by the newer radioactive iron procedures for red cell volume.

JOHN R. WOLFE, M.D.

Thrombophlebitis in Pregnancy G. D. MATTHEW. *Edinburgh M. J.* 94:7 54-64.

The overall incidence of thrombophlebitis and pulmonary embolism is in the region of 2 per cent at the Simpson Maternity Pavilion. The incidence rises in caesarean section to about 4 per cent. During the past 20 years there have been 17 reported deaths from pulmonary embolism. The location of veins involved in thrombophlebitis is essentially the same in obstetric and nonobstetric patients with the exception of the deep pelvic veins. In the 17 fatal cases mentioned only 7 showed clinical evidence of thrombosis affecting the veins of the pelvis or lower limbs.

Fifty consecutive cases of thrombophlebitis without specific therapy are compared with 19 cases treated with heparin. Unfortunately an adequate supply of heparin was not always available and in some cases the supply was insufficient to complete the course of treatment. Of the 19 patients treated 16 suffered from thrombophlebitis of the pelvis and/or lower limbs being regarded as deep and 3 as superficial. In the remainder 1 patient had thrombophlebitis in the arm following intravenous therapy and 2 patients had pulmonary embolism. There was a higher incidence of abdominal section in the heparin treated cases (42%) as compared with the control series (26%).

All of the patients responded rapidly to heparin therapy with 3 exceptions. Embolism occurred in both of these—in one after premature interruption of

atment and in the other a full course of treatment was rendered impossible because of insufficient supplies. One of the main hopes in heparin therapy is marked reduction in the period of hospitalization. The average difference in hospitalization between the heparin-treated and the control was 1 week. GEORGE BLUMICK M.D.

Hemorrhage in Pregnancy J. KENWORTHY OGDEN *Brit. M. J.*, 1948 1: 389.

A case of eclampsia complicated by an accidental retroperitoneal hemorrhage is described. Conservative management of the hemorrhage had to be abandoned in favor of classical cesarean section because of the fact that the uterus remained obstinately tense, and sudden increase in retroperitoneal hemorrhage made immediate operative intervention imperative. The patient made a smooth recovery until the fourth postoperative day when she died suddenly of severe retroperitoneal hemorrhage.

At autopsy a massive retroperitoneal hemorrhage was found which seemed to originate in the region of the junction of the body and neck of the pancreas. The hemorrhage burst through the peritoneum of the lesser sac and from 4 to 5 pints of blood passed through the aditus of the lesser sac into the general retroperitoneal cavity.

Six previously reported cases of retroperitoneal hemorrhage occurring during pregnancy are reviewed. In 3 cases, a condition of toxemia of pregnancy was present. One of the outstanding features of the pathology of eclampsia is capillary thrombosis followed by extravasation of red blood cells and the author wonders as to whether or not a similar condition might happen in vessels of larger caliber in isolated instances. GEORGE BLUMICK M.D.

LABOR AND ITS COMPLICATIONS

Premedication and Anesthesia in Obstetrics: Practical Aspects. BRIT. B. HENDERSON *Acta Obstet. Gynecol.* 1948 9: 73.

The author states that the purpose of his paper is two-fold: (1) to consider some of the essential principles that are basic to any plan of premedication and anesthesia in obstetrics and (2) to present the practical aspects of the problem as experienced at the Boston Lying in Hospital. He discusses the aims of an ideal premedication from the standpoint of the mother, the obstetrician and the anesthesiologist, but believes that the ideal agents or techniques to accomplish the objectives he outlines are not yet available. He emphasizes the over-all capabilities of the obstetrical team as being the real determinants of the degree of safe relief for mother and child.

The use of scopolamine with combinations of various drugs is discussed, and the advantages and disadvantages are thoroughly covered. It is believed that scopolamine is the best amnesic available and the author has noted no demonstrable ill effects on the fetal or neonatal vital functions. It may be given subcutaneously intramuscularly or

intravenously with shortened periods of maximum effect from the time of administration. It is noted that scopolamine will occasionally produce edema of the eyelids, lips, or uvula, and that its cortical effect, the production of excitement is present in about 40 per cent of obstetrical cases.

Four different periods in which different amnesics were used are summarized. In the present period scopolamine is utilized as a preliminary sedative early in labor to relieve apprehension and when labor is well established a combination of scopolamine and apomorphine is used. Apomorphine is administered to allay the exciting effects of the scopolamine. The initial dose is 1/100 grain of each followed by repeat doses of 1/150 gr. scopolamine and 1/50 gr. apomorphine. Three cases are presented in detail. All 3 patients had normally progressing labors which terminated successfully and in which the mother had no memory after the initial injection.

The use of barbiturates is summarized on the basis of previous reports from the Boston Lying in Hospital. Their advantages and disadvantages are outlined in detail and the analysis is favorable to them. However one of the disadvantages—respiratory complications—is worthy of mention. The most serious complication is pulmonary edema with a clinical picture of stertorous respiration, dyspnea, laryngeal spasm, bronchospasm, increased bronchial secretions with bubbling rales throughout the lung fields, diminution of minute-volume, respiratory ventilation, cyanosis, tachycardia, and a fall in the blood pressure. Nembutal was found to produce this complication twice as often as any of the other barbiturates used. GEORGE B. DRABURN M.D.

Continuous Caudal Analgesia. ROBERT A. HINCHSON, WALDO B. EDWARDS, CLIFFORD B. LULL, FRANK E. WHITACRE and H. CHARLES FRANKLIN *J. Am. M. Ass.* 1948 136: 221.

At the time of the present analysis 600,000 cases had been reported in which labor and delivery were managed under continuous caudal analgesia. All of the reports have emphasized the well being of the newborn infant. In spite of this certain disadvantages to the fetus are apparent. Hypotension as a result of the nerve block of vasomotor nerves may result in intrauterine anoxia. Too early administration or an anesthetic level that is high enough to interfere with uterine motility may cause arrest or prolongation of the labor with increased trauma. The incidence of operative delivery is increasing because of the absence of expulsive powers. Fetal hypersensitivity to the drug that is used may occur.

The authors report a total of 7,803 births—5,059 under caudal anesthesia and 2,834 under other forms of anesthesia. The analysis clearly reveals that less respiratory difficulty was experienced with the use of continuous caudal anesthesia than with any other method. The same conclusion was reached with regard to the number of stillbirths and neonatal deaths. An analysis of differences in weight gain failed to reveal any significant data.

The authors point out (Memphis group) that the stillbirth rate for deliveries without the aid of anesthesia was 80.4 per thousand live births, the neonatal mortality being 63.6 per thousand live births in the same group. This was compared to the 18.4 rate for both stillbirth and neonatal deaths in cases in which caudal anesthesia was used. With spinal anesthesia, the stillbirth rate was found to be 45.2 per thousand live births and the neonatal death rate 29.0 per thousand live births.

The authors failed to draw any conclusions from their analysis.

JAMES F. DORRILEY, M.D.

Pelvic Delivery following Cesarean Section. DAMEL H. HINDMAN. *Am J Obs* 948, 55: 273.

During the interval from January 1, 1938 to January 1, 1947, there have been effected at the Boston Lying-in Hospital 177 deliveries through the natural birth passage in 118 patients who had previously been subjected to cesarean section. Thirty of these women were delivered twice subsequent to hysterotomy 7 three times, and 3 four times and 1 was delivered five times and another six times respectively. There was one maternal mortality in the series, ascribed to aspiration pneumonia. The great proportion of these patients had been subjected to cesarean section for a temporary indication.

The fundamental question revolves about the behavior of the uterine scar in subsequent pregnancies

whether it shall prove adequately firm to tolerate the distention of the uterus as pregnancy advances and to withstand the stress of labor itself. The functional strength of the scar is intimately dependent upon the histology of wound healing in the uterus and the location of the incision. The literature is reviewed in regard to the anatomic study of these scars. The author presents in some detail the 8 cases of disruption of a cesarean scar in a subsequent pregnancy. Two such accidents occurred in patients who were selected for prospective delivery through the pelvis. Only 1 of these patients experienced labor.

Precautions to be followed in the selection of cases, instructions to the patients, and instructions on the management of labor and delivery are presented. The technique of manual exploration of the uterine cavity following delivery is given in detail.

From an analysis of the cases presented and a review of the literature, the author concludes that in properly selected patients who have been previously subjected to cesarean section for some temporary indication, attempts at pelvic delivery are to be encouraged, provided certain precautions are observed. By pursuit of such a policy, one may anticipate not only a considerable curtailment in the frequency of cesarean section but a gratifying reduction in maternal mortality and morbidity as well as some conservation of hospital days.

JOHN R. WOLFE, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Treatment of Renal Insufficiency GEORGE W. THORN *J Urol* Balt., 1948 59 119.

Three major problems in therapy of renal insufficiency are discussed (1) nephrotic edema (2) remediable types of chronic uremia, and (3) "lower nephron nephrosis." Generalized edema is most often the most incapacitating factor and this is occasioned principally by increased retention of sodium and chloride, disturbances of protein metabolism characterized by proteinuria and hypoalbuminemia and cardiac failure secondary to renal dysfunction. None of the therapeutic agents available have any effect on the underlying renal pathology but they will tend to assist in controlling the edema. This subject is admirably discussed. The preferred therapeutic agents are restricted sodium chloride, the administration of urea in patients without azotemia, and concentrated human serum albumin intravenously specifically the latter.

Under the heading of "remediable types of chronic uremia" the author discusses various types of chronic uremia that may be modified with prolongation of life. He considers (1) obstructive uropathy (2) chronic hyperparathyroidism with renal calcinosis (3) chronic pyelonephritis without hypertension (4) "salt losing" type of chronic nephritis (5) irradiated sternal intoxication and (6) subacute bacterial endocarditis. In short it is believed that any form of chronic uremia unassociated with hypertension, edema, or cardiac failure bears careful investigation since there is a strong possibility that the patient may be offered an additional period of useful life. The factors of therapeutic importance are (1) a fluid intake of 2500 to 3000 c.c. daily (2) maintenance of a normal serum chloride level (3) limitation of protein to 50 grams daily (4) transfusions as necessary or washed red cells as indicated (5) intravenous glucose and saline infusions as needed to control azotemia (6) aluminum hydroxide to reduce hyperphosphatemia and (7) serum albumin as needed for hypoproteinemia and edema. The warning of misinterpreting hypochloremia due to carbon dioxide-chloride shift is mentioned since the use of sodium chloride in this type of hypochloremia is contraindicated. The associated urinary tract infections are treated with the sulfonamides or antibiotics, which ever seems indicated by carefully executed bacteriological studies. The value of sulfonamide combinations and alkalinization in conjunction with streptomycin therapy is emphasized.

The author discusses "lower nephron nephrosis," a pathological entity common to a wide variety of damaging agents i.e. intravascular hemolytic reactions crushing injuries, burns nontraumatic muscular ischemia sulfonamide intoxication and toxemia of pregnancy. The treatment of this condition is

considered under three headings (1) emergency, (2) maintenance during oliguria and anuria, and (3) reparative treatment during the early phase of diuresis. During the first phase, renal vasoconstriction and ischemia are of prime consideration. During the phase of oliguria and anuria the limitation of fluids so as to prevent flooding the body is essential, as well as the need for the administration of basic caloric requirements and the use of digitals in the event of cardiac incompetency. In the third phase the chloride level must be watched for purposes of replacement or as occurs in damage from sulfonamides for sudden increase in chloride which is to be handled by the administration of salt-free fluid to wash out this increasing chloride level in the blood and thus obviate cerebral edema and death.

The article is exceptionally well illustrated and includes statistical data. Case reports are used to emphasize the diagnosis and therapy.

ROBERT LICH, JR. M.D.

Traumatic Pseudohydronephrosis (Pseudohydronephrosis traumatica) JULIO V. URIBURU and OSCAR C. CARRASO *Prosta mid argent* 1948, 35 174.

Traumatic pseudohydronephrosis is the term designating the infiltration or collection of urine and blood in the perirenal adipose tissue occasioned by rupture of the kidney. For this condition to occur it is necessary for the rent to include the pelvis or calyces of the kidney. Traumatic rupture of a ureter, an exceedingly rare condition may also initiate pseudohydronephrosis. The latter condition, although certainly grave does not reach the seriousness of urinary extravasation from the bladder.

Rupture of the urinary tract at the level of the bladder or of the pelvis or calyx of the kidney produces extravasation of urine and blood which first infiltrates progressively the adipose tissue and later transforms the walls into cystic sacs which contain either clear urinary fluid or dark liquid consisting of urine and clotted blood. The kidney appears to be displaced and in contact with the sac, the cavity of which generally is in communication with the urinary tree. A pure lesion of the parenchyma does not give an infiltration of urine.

The diagnosis is dependent upon the antecedent history of trauma and generally the presence of intense contusion over the lumbar region. Signs of a renal lesion, pain, and hematuria occur immediately. Most authors believe that a swelling appears early. In the chronic stage, the differentiation from a renal cyst is impossible. Flat films of the abdomen reveal a dense diffuse mass in the affected area. With the nearby organs filled with radiopaque material the stomach may be demonstrated to be elevated and elongated the colon is pushed downward and its lumen is narrowed. The position of the swelling will influence the roentgenogram. The secreting

Fig. (Uniforu, Carrefu) Radiogram of barium enema showing displacement of the descending colon and compression of the lumen by the tumor

function of the kidney on the affected side is diminished as evidenced by intravenous pyelography. Retrograde pyelography is also of diagnostic value.

A differential diagnosis must be made from rupture of a pre-existing hydronephrosis, traumatic hydronephrosis and pseudohydronephrosis. Appearance of a swelling immediately following trauma suggests a perirenal hematoma. Hematonephrosis which yields red blood cells in the urinary tract develops late and is extremely rare.

If the quantity of urine extravasated is small it may resorb. If organization occurs a chronic sclerosing perinephritis may result. However the extravasation is usually so great that resorption is impossible. Frequently infection of the contained fluid supervenes and surgical intervention becomes imperative. The function of the kidney on the affected side which may be inhibited by compression after operation is recovered. In the case reported, 15 days after operation the kidney eliminated indigo-carmin after 15 minutes, and a little after a month the indigocarmine was eliminated at 4½ minutes.

If operation is delayed until after the development of toxic phenomena and infection the prognosis is considerably more grave. Occasionally the pathological anatomy of the lesion may necessitate nephrectomy.

Once the diagnosis of pseudohydronephrosis is established immediate operation is imperative. Two points are stressed: the cystic pouch should be emptied and the kidney should not be touched.

Rapid drainage of a large cyst will cause shock. A fistula may be left to drain to the surface and this will generally close spontaneously. Nephrectomy or partial nephrectomy is reserved for selected cases.

The case history of a young man who received severe trauma to the left lumbar region is reviewed. The swelling in the left flank appeared a month after the initial trauma. Intravenous pyelography revealed good function of the right kidney but none of the left. At operation 6 liters of urousanguineous liquid were obtained. A portion of the sac was resected, sulfanilamide placed in the wound, and rubber dams were inserted. Recovery was uneventful and kidney function on the left side returned.

HAROLD W. BACCHOFF, M.D.

Lymphatic Cysts of the Kidney A. J. SCHOLL, J. Am. M. Ass. 1945, 1364.

Peripelvic cysts of the kidney occur only rarely; they are usually small in size and in most cases they have been noted by pathologists as incidental findings at autopsy. In only a few cases have cysts of this type caused clinical symptoms. In these, the cysts were usually large and tended to distend the abdomen. In the majority of cases their peripelvic origin was recognized only on the operating table or at autopsy.

Two cases of lymphatic cysts of the kidney are reported in detail. At operation, both patients were found to have large peripelvic lymphatic cysts which were of sufficient size to cause distortion of the renal pelvis and to exert pressure on the structures of the renal hilus. These cases are of interest because of the origin and large size of the cysts, their apparent relationship to hypertension, and the similarity of the diagnostic signs to those of renal tumors.

The cysts in both cases were exceptionally large for this type of lesion and the kidney was removed in each case. The first patient was elderly and hypertensive; there was considerable destruction of the kidney and it was impossible to determine definitely whether the lesion was simply cystic or whether malignant growth also was present. Similar conditions were present in the second case except that the lower segment of the cyst was viable and protruded from the renal hilus. When the cyst was opened, uncontrollable bleeding was encountered from a large vessel in the deeper portion of the cyst. An attempt was made to control the bleeding by packing and suturing without success, and it was necessary to remove the kidney. On examination of the kidney after removal a fairly large ruptured blood vessel was found in the cystic cavity. In both kidneys there was evidence of previous inflammation, a probable causative factor in the formation of lymphatic cysts.

The effect of removal of the cysts on the elevated blood pressure was of interest. Apparently the cysts were so located as to cause a partial constriction of the renal artery, a condition which has been shown by experiments of Goldblatt and others to cause renal ischemia and hypertension. The fall in blood pressure followed immediately after operation, and while

remained low in one case for a year insufficient time has elapsed in either case to predict where it will eventually become stabilized

Peripelvic lymphatic cysts of the kidney usually small and of little clinical importance may become of sufficient size partially to destroy the kidney these cysts are probably lymphatic ectasia associated with obstruction of the lymphatic trunks of the hilus of the kidney Lymphatic cysts add one more to the list of types and the theories of development of renal cysts

JOHN E. KIRKPATRICK, M.D.

Papillomas of the Kidney Pelvis and of the Ureter
(I papillomi del bacinetto e dell' uretere) GIOVANNI BRAVETTA. *Arch. ital. urol.* 1947 22 1

Three cases of papillomas of the kidney pelvis and ureter are reported. The first was that of a 60 year old male who 4 years previously had experienced a sudden massive hematuria which allegedly varied in severity but never ceased since that time. For about a year the patient occasionally suffered from cramp-like pains in the abdomen and had some discomfort about the left kidney region. For about a month he has been very weak from anemia. Operation disclosed a number of large pea-sized rounded pedunculated masses, one of which had resulted in some dilatation of the superior calyx and another was attached to the point of egress of the ureter from the renal pelvis. The author does not know how to explain the uninterrupted bleeding in this case and simply adds this peculiarity as another possibility in the clinical behavior of this type of tumor.

In the second patient, a 55 year old male the clinical picture was initiated as a total hematuria lasting a week, with violent pains radiating from the left flank to the waist line (which resembled the girdle pains of tabes) vomiting and some fever. Fifteen days later there was another attack minus the fever and girdle pains. After passing the blood the patient was relieved. Operation in this case disclosed a hugely dilated kidney in which all resemblance to organized kidney structure was practically destroyed. The cavity thus produced was filled with an orange-sized, villous tumor mass attached exclusively to the wall of the renal pelvis and showing no connection whatever with the kidney tissues. This mass did not penetrate through the embouchure into the lumen of the ureter however about 2 cm. below this opening there was a warty-appearing excrescence on the ureteral mucosa and about two thirds of the way down the lumen of the ureter was filled for a distance of 7 cm. with a papillomatous mass. This neoplasm resembled in general that in the kidney pelvis but was more compact and loosely adherent to the ureteral walls in several places. In addition to having several points of true attachment by means of slender pedicles. The rest of the ureter appeared normal however in the bladder the cystoscope disclosed a diffuse specific cystitis. The question arose as to infection in the origin and spread of these neoplasms.

The third patient, a 66 year old hypertensive female suffered a single attack of total hematuria

without other symptoms. The patient lost weight but did not notice blood in the urine however at examination the left ureter was patently emitting blood. Operation in this instance again disclosed a walnut-sized papilloma in the moderately dilated renal pelvis. There was a smaller mass independently attached near the pedicle of the main tumor. In this case the bleeding recurred 2 1/2 months later and cystoscopy disclosed a papillomatous mass at the cupula of the bladder which was attached to the cupula of the bladder. This mass had been removed by electrocoagulation. This mass had definitely not been present at the time of operation and led to the theory that detached bits from the original papilloma may remain vital and become reattached lower down in the urinary passages.

JOHN W. BRENNAN, M.D.

Histologic Revision of the Process of Repair of Kidney Wounds Resulting from Partial Nephrectomy
(Revisión histológica del proceso de reparación de las heridas renales por nefrectomía parcial) LUCIANO AZAGRA. *Arch. españ. urol.* 1947 4 160.

Ten dogs were subjected to partial nephrectomy. The amount of kidney removed was about 10 per cent of the weight of the whole organ. In alternate animals homoplastic inserts of muscle or fatty tissue (epiploon) were placed in the breach left by the partial nephrectomy. In the remaining animals the two bleeding kidney surfaces were simply squeezed together for several minutes without the use of any other form of hemostasis. In all of the cases the capsule and edges of the renal wound were approximated and stitched together with interrupted sutures. Then in from 2 to 25 days after the partial nephrectomy total nephrectomy was done and the specimens thus procured were sectioned histologically and stained with hematoxylin-eosin. The sections were chosen to disclose the results obtained from the first operation.

In the kidneys in which the homoplastic insert was of muscle tissue there were observed remnants of striped muscle fibers in all stages of degeneration of fibers which appeared to be infiltrated by round cells and hemorrhagic portions of kidney tissue with edema. There was no evidence in these sections of any revitalization of the tissue inserts. Occasionally in these sections there were accumulations of epithelial cells evidently arising from the kidney tubules and some of these cells showed mitoses. However these accumulations of epithelial cells never showed any inclination to form tubules themselves. In the zone contiguous to the muscle insert an abundance of dilated capillaries was observed these capillaries looped about among the renal tubules which were themselves in the process of degeneration but nowhere was there any evidence of an attempt at new formation of glomeruli.

In the animals in which the inserts were of fatty tissue, no vestiges of these implants could be found even in the most recent specimens. In these specimens as in those without inserts there were simply an increase and tortuosity of the capillaries about

the line of contact of the incised surfaces and an afflux of red and white blood cells together with degeneration of the tubules and glomeruli in the cutaneous. All these changes lost in intensity as the distance from the line of incision increased.

In one specimen of a partially nephrectomized kidney from a patient who died of shock 24 hours after operation the described changes were present but the degenerative manifestations were much more marked and at a much greater distance from the incised surfaces. In this case an electric scalpel had been used to make the incisions.

Complete histologic description of the entire process of injury and repair is not given but only those processes which might throw some light on the subject under discussion are considered.

JOHN W. BRENNAN, M.D.

Transvaginal Ureterorectal Anastomosis. HERBERT D. WOLFF JR. *J. Urol. Balt.* 1945, 59, 18.

The author stimulated by the work of Hanner and Shaw on ureterorectal anastomosis with cystectomy, decided to apply that technique in a patient having an infiltrating malignancy of the trigone of the bladder.

The patient was a 73 year old white nullipara who complained of gross hematuria. Cystoscopy revealed an ulcerated lesion of the trigone measuring 3 by 2 cm. with levated nodular edges. It extended to within 1 cm. of the right ureteral orifice and 1.5 cm. of the left ureteral orifice when the bladder was distended and involved the vesical orifice from 5 to 8 o'clock. There was also a separate pedunculated papillary tumor located at 9 o'clock near the vesical orifice. The papilloma was removed with the resectoscope and biopsy of the trigonal ulcer revealed a grade III infiltrating epidermoid carcinoma. The rest of the patient's work-up was essentially normal.

Preoperative preparation included daily catharsis, a low residue diet with concentrated carbohydrates and vitamins, and sulfasuxidine orally.

Operation was performed on May 4, 1946. Transvaginal ureterorectal anastomosis with partial cystectomy was done under spinal anesthesia. A midline epiflotomy was done for exposure. The cervix was pulled down Young's prostatic retractor was inserted through the urethra and gave traction. The urethra was dissected free and the anterior vaginal incisions were made elliptical to allow removal of the vaginal vault beneath the tumor. The anterior bladder wall, dome and lateral walls were freed with surprising ease. The anterior bladder wall was then incised transversely to expose the tumor and ureteral orifices. The ureters were easily catheterized and drainage was good. The transverse incision was extended to leave a cuff of bladder wall around the left ureteral orifice but it was made close to the lower edge. Thus, the bladder neck and urethra were amputated. The right ureter was cut at the ureterovesical junction. All of the liberated bladder was excised, but the posterior wall was allowed

to remain. This residual portion was to be excised if time permitted or used as the anterior vaginal vault. The rectum was then exposed by extension of the midline epiflotomy incision. The lateral vaginal walls near the cervix were tunneled under by blunt dissection, and the ureteral catheters which had been tied in the ureters were grasped and brought down. The muscularis was separated and the rectal mucosa exposed at the sites selected for anastomosis. A short proctoscope was passed the mucosa incised left and right and the catheters were passed through the proctoscope. The ureters were drawn into the rectum and anchored with the usual transfixion sutures and with sutures of oo chromic catgut to the muscularis. The remaining posterior bladder wall fitted into the anterior area of the excised vagina. It was sutured in place and the posterior vaginal wall was then resutured. The epiflotomy was closed.

The operation took 3 1/2 hours and was tedious but not as difficult as had been anticipated.

The postoperative course was essentially uncomplicated. The patient received penicillin and transfusions, and was kept on an acid ash diet. Both ureteral catheters drained perfectly and they were left in until they came out spontaneously on the eighteenth postoperative day. An intravenous urogram showed a normal right urinary tract and a moderately dilated left one. Anal control was fair and the patient left the hospital 1 month after the operation.

Two and one half months postoperative she noticed leakage of urine from the vagina in small amounts. An intravenous urogram revealed a normal right urinary tract but no dye appeared in the left pelvis or ureter in 60 minutes. Proctoscopy showed a small hyperemic mound in the area of the right ureteral transplant with urinary drainage. The left ureteral orifice was represented by a small dimpled orifice just within the anus. Catheterization of the left ureteral orifice was at first unsuccessful. Finally a No. 4 F. form was passed and dilated to No. 8. Following this dilatation and drainage there was no reaction and the urinary leakage ceased at once. Subsequently the left ureteral orifice was dilated every 1 to 3 weeks up to a No. 22 bulbous catheter to which resistance was marked. At no time was the dilating catheter passed more than 6 to 8 cm. up the left ureter and neither lavage nor retrograde pyelography was done. The urinary stasis decreased as did the amount of pus in the urine. The anterior vaginal wall was found to be bulging into the vaginal orifice with localized edema. This was controlled with a small doughnut pessary.

Re-examination in February 1947, after the pessary had intentionally been left out for a week, revealed the anterior vaginal wall herniating through the vaginal orifice with localized bleb edema. Indigo carmine given intravenously appeared in fair concentration from both ureterorectal orifices in 10 minutes. An intravenous urogram showed fairly normal upper urinary tract.

From his experiences with this case the author feels that transvaginal ureterorectal anastomosis in the

female with normal vaginal structures is possible. The advantages of the approach seem to be (1) an easier single stage procedure with minimum shock (2) an extraperitoneal approach with safety from peritoneal infection and from intestinal obstruction (3) the accessibility of the lower ureters for trans rectal instrumentation and (4) the reserve possibilities of a secondary transvaginal ureterorectal anastomosis or ureterosigmoidostomy if the primary procedure is unsuccessful. He states that further experience will be necessary to establish these advantages and feels that the procedure is worthy of consideration in certain cases of urinary incontinence, vesicovaginal fistula, elusive ulcer and for tumors of the bladder neck and urethra.

ROBERT O. BEADLES, M.D.

Modern Concepts of Ureteral Calculi. CHARLES C. HIGGINS and J. G. WARDEN. *Ann. Surg.* 1948 127: 257

The authors review a series of 256 cases of ureteral calculi for the purpose of comparing the method of treatment instituted with that used in previously reported series. The present article is a supplementary report on ureteral calculi treated at the Cleveland Clinic, Cleveland, Ohio during the period from 1939 to 1945.

It is generally accepted that no single etiologic factor is responsible for the formation of the calculi; therefore, in view of our present knowledge, the following factors must be studied: (1) hyperparathyroidism, (2) vitamin A deficiency, (3) stasis, (4) metabolic diseases, (5) focal infection and (6) in infections of the urinary tract.

In 69 per cent of the cases the condition occurred between the ages of 21 and 50; 79 per cent of the patients were men and 21 per cent were women. In 47 per cent of the patients the calculi were located in the right ureter and in 53 per cent in the left ureter. Bilateral ureteral calculi occurred in 17 to 3.6 per cent of the cases. The majority of calculi were found to be impacted in the pelvic portion of the ureter.

Pain was the predominant symptom. It occurred as colic in 59 per cent of the patients as unilateral costovertebral-angle pain in 20 per cent, as indefinite abdominal discomfort in 22 per cent, and as nausea and vomiting in 36 per cent of the patients.

Calculi in the upper ureter produce pain either as a colic radiating around the abdomen to the epigastria or by obstruction produce a fixed sharp or dull pain in the posterior renal area. Stones in the pelvic portion of the ureter may produce colic, obstructive symptoms and also pronounced vesical symptoms. During the attack nearly half of the patients in the series noted frequency. Urgency was present in 31 per cent. Microscopic hematuria was present in 83.8 per cent of the patients and gross hematuria in 36.7 per cent. Microscopic pus was present in 89 per cent.

Ninety-eight per cent of stones were demonstrated roentgenologically. Intravenous urography has become an important diagnostic aid. In addition to demonstrating opaque and opaque stones, a

physiologic picture of renal function is secured thereby by fixing an index of the proper therapeutic course to be followed.

Few urologic problems require consideration of so many factors as does an obstructing ureteral calculus. Whether to operate or manipulate is the question arising in every case. The economic status of the patient and his occupation may influence the procedure to be advocated. A sudden attack of colic in persons working as airplane pilots, engineers, etc., may endanger the lives of those dependent upon them. Repeated attacks of colic in a laborer may result in a greater loss of working time than if surgical removal was done.

The size of the calculus is of considerable importance as a general rule the larger the calculus the less likely it is to pass spontaneously, and the more frequently will manipulative efforts fail to succeed.

Any method of therapy should have as its prime objective the prevention of destruction or loss of function of the kidney on the affected side.

The general health of the patient is a factor inasmuch as some patients are more susceptible to febrile reactions following manipulative procedures. In elderly patients associated pathological conditions such as prostatic hypertrophy make manipulative procedures technically difficult and febrile reactions are more likely to occur. In small children because of technical difficulties open operation is usually the procedure of choice.

In the authors' experience the use of single or multiple catheters has been most successful with minimal complications. They believe that mechanical stone removers should be restricted to use on stones in the lower third of the ureter. Stones of the upper and midureter are in the absence of complications treated by a policy of watchful waiting. If the calculus is 1 cm. in diameter or less and is moving spontaneously down the ureter manipulative treatment is delayed until the stone reaches the pelvic portion then the use of multiple catheters or a basket extractor is advised. If the stone in the mid or upper ureter is producing complete obstruction then surgical intervention is advocated.

Spinal anesthesia is the anesthesia of choice for the surgical removal of stones from the ureter. Immediately before operation it is advisable to check the location of the calculus roentgenographically.

A muscle-splitting operation and extraperitoneal approach are utilized in removing stones from every point of the ureter.

In the authors' experience operation has been resorted to for the following reasons: (1) repeated failure of manipulative methods, (2) impassable obstructions due to stones that cannot be moved, (3) renal infections which endanger the life of the patient by temporization, (4) associated disease which makes instrumental attempts technically impossible, (5) upper urinary tract disease which itself requires surgery, and (6) in patients who cannot tolerate transurethral manipulation. In conclusion the authors state that investigation of the numerous etiologic

the line of contact of the incised surfaces and an afflux of red and white blood cells together with degeneration of the tubules and glomeruli in the environs. All these changes lost in intensity as the distance from the line of incision increased.

In one specimen of a partially nephrectomized kidney from a patient who died of shock 24 hours after operation, the described changes were present but the degenerative manifestations were much more marked and at a much greater distance from the incised surfaces. In this case an electric scalpel had been used to make the incisions.

Complete histologic description of the entire process of injury and repair is not given, but only those processes which might throw some light on the subject under discussion are considered.

JOHN W. BRECKMAN, M.D.

Transvaginal Ureterorectal Anastomosis. HERBERT D. WOLFE, Jr. *J. Urol. Balt.* 64:3, 59, 8

The author stimulated by the work of Hunner and Shaw on ureterorectal anastomosis with cystectomy decided to apply that technique in a patient having an infiltrating malignancy of the trigone of the bladder.

The patient was a 73 year old white male para who complained of gross hematuria. Cystoscopy revealed an ulcerating lesion of the trigone measuring 3 by 2 cm. with elevated nodular edges. It extended to within 1 cm. of the right ureteral orifice and 1.5 cm. of the left ureteral orifice when the bladder was distended and involved the vesical orifice from 5 to 8 o'clock. There was also a separate pedunculated papillary tumor located at 9 o'clock near the vesical orifice. The papilloma was removed with the resectoscope and biopsy of the trigonal ulcer revealed a grade III infiltrating, epidermoid carcinoma. The rest of the patient's work up was essentially normal.

Preoperative preparation included daily catharsis, a low residue diet with concentrated carbohydrates and vitamins, and sulfasuxidine orally.

Operation was performed on May 4, 1946. Transvaginal ureterorectal anastomosis with partial cystectomy was done under spinal anesthesia. A midline episiotomy was done for exposure. The cervix was pulled down. Young's prostatic retractor was inserted through the urethra and gave traction. The urethra was dissected free and the anterior vaginal incisions were made elliptical to allow removal of the vaginal vault beneath the tumor. The anterior bladder wall, dome and lateral walls were freed with surprising ease. The anterior bladder wall was then incised transversely to expose the tumor and ureteral orifices. The ureters were easily catheterized and drainage was good. The transverse incision was extended to leave a cuff of bladder wall around the left ureteral orifice but it was made close to the lower edge. Thus, the bladder neck and urethra were amputated. The right ureter was cut at the ureterovesical junction. All of the liberated bladder was excised but the posterior wall was allowed

to remain. This residual portion was to be covered if time permitted or used as the anterior vaginal vault. The rectum was then exposed by extension of the midline episiotomy incision. The lateral vaginal walls near the cervix were tunneled under by blunt dissection and the ureteral catheters which had been tied in the ureters were grasped and brought down. The muscularis was separated and the rectal mucosa exposed at the sites selected for anastomosis. A short proctoscope was passed, the mucosa incised left and right and the catheters were passed through the proctoscope. The ureters were drawn into the rectum and anchored with the usual transfexion sutures and with sutures of 00 chromic catgut to the muscularis. The remaining posterior bladder wall fitted into the anterior area of the excised vagina. It was sutured in place and the posterior vaginal wall was then re-sutured. The episiotomy was closed.

The operation took 2 1/2 hours and was tedious but not as difficult as had been anticipated.

The postoperative course was essentially uncomplicated. The patient received penicillin and transfusions, and was kept on an acid ash diet. Both ureteral catheters drained perfectly and they were left in until they came out spontaneously on the eighteenth postoperative day. An intravenous urogram showed a normal right urinary tract and a moderately dilated left one. Anal control was fair and the patient left the hospital 2 months after the operation.

Two and one-half months postoperative she noticed leakage of urine from the vagina in small amounts. An intravenous urogram revealed a normal right urinary tract but no dye appeared in the left pelvis or ureter in 60 minutes. Proctoscopy showed a small hyperemic mound in the area of the right ureteral transplant with urinary drainage. The left ureteral orifice as represented by a small dimpled orifice just within the anus. Catheterization of the left ureteral orifice was at first unsuccessful. Finally a No. 4 B₁ form was passed and dilated to No. 8. Following this dilatation and drainage there was no reaction and the urinary leakage ceased at once. Subsequently the left ureteral orifice was dilated every 2 to 3 weeks up to a No. 11 bulbous catheter to which resistance was marked. At no time was the dilating catheter passed more than 6 to 8 cm. up the left ureter and neither lavage nor retrograde pyelography was done. The urinary stasis decreased as did the amount of pus in the urine. The anterior vaginal wall was found to be bulging into the vaginal orifice with localized edema. This was controlled with a small doughnut pessary.

Re-examination in February 1947 after the pessary had intentionally been left out for 3 weeks, revealed the anterior vaginal wall herniating through the vaginal orifice with localized bleb edema. Indigo carmine given intravenously appeared in fair concentration from both ureterorectal orifices in 10 minutes. An intravenous urogram showed a fairly normal upper urinary tract.

From his experiences with this case the author feels that transvaginal ureterorectal anastomosis in the

are of three general types (1) fibrous contractures or bars (2) intravascular hypertrophy, and (3) subvesical enlargement the last two may exist in combination.

Several years ago the author called attention to the fact that a certain danger existed in the period of preoperative preparation and that a mortality occurred which in many instances could be attributed to infection initiated by urethral instrumentation often arising from the use of the indwelling urethral catheter. The use of suprapubic puncture was suggested as a safer procedure and subsequent and extended experience has fortified this attitude.

The operation itself is the least important phase of the patient's hospital sojourn and yet one must acknowledge its contribution to the safety of prostatic surgery. The older authors recognized three great dangers in prostatic surgery (1) shock (2) hemorrhage, and (3) uremia. The last of these has been largely overcome by proper preoperative study of renal function and preparation of the patient to improve and stabilize the kidney function. An associated factor of great importance is the avoidance and control of urinary infection which was all too often the immediate cause of the uremia.

Undue bleeding should first be combated by irrigation and blood transfusion, but one cardinal principle should always be observed namely, a bladder filled with clots must be emptied with the least possible delay. For this purpose the most certain and satisfactory method is to return the patient to the operating room where under pentothal anesthesia, the resectoscope is introduced and all clots evacuated.

The blood pressure must be carefully watched and any sudden or progressive drop promptly combated. The use of vasoconstrictor drugs may suffice for immediate use but in the case of shock blood must be available for transfusion. An available blood bank may thus become a potent safety factor.

The postoperative fluid intake must be properly maintained and in the days immediately following operation, reliance is placed mainly upon intravenous administration. Five per cent glucose in saline is employed in patients who have undergone prostatectomy at least 3,000 c.c. are given daily.

Urinary sepsis with ascending pyelonephritis has in the past accounted for a considerable number of fatalities. Previously the author has commented on the value of sulfonamides and antibiotics. Patients are given, routinely 20,000 units of penicillin every 3 hours along with 7½ gr. of sulfathiazole four times daily. This is discontinued on the fourth day unless particular indications demand continuance.

Epididymitis is controlled by vasectomy it is practically routine for patients having a prostatectomy but is rarely done in patients having transurethral resection because the incidence of epididymitis is very low.

Embolie episodes have long been a much dreaded complication of prostatic surgery. Thrombophlebitis which involves the veins of the legs is rarely encountered and it is believed that emboli originate more often from the periprostatic and deep pelvic

veins. The author prefers to treat thrombophlebitis with the anticoagulants. Heparin is used if immediate response is imperative dicumarol is used in less urgent cases and for those in which prolonged treatment seems desirable.

JOHN A. LOFF, M.D.

Torsion of the Appendix Testis. WILLIAM M. COPPELDORE and LOUIS C. ROBERTS. *J. Pediat.*, St. Louis, 1948 32: 184.

Acute painful swelling of the scrotal contents in young boys is seen infrequently. Injury or torsion of the spermatic cord accounts for the majority of cases. Torsion of the appendix testis though rare is seen sufficiently often to call for its consideration in the differential diagnosis in this group of cases.

The appendix testis is attached to the upper extremity of the testis just beneath the head of the epididymis. It is said to be present in 90 per cent of males and varies from 5 to 10 mm. in length. The structure is attached to the connective tissue investing the testis and consists of vascular connective tissue containing a canal lined with columnar epithelium. The appendices testes are in fact the persisting cephalic ends of the embryonic müllerian ducts which in the female develop into the oviducts uterus and most of the vagina.

Torsion of this small vestigial body produces symptoms often confused with other acute pathology of the scrotal contents or of intra-abdominal disease. The severity of the symptoms is usually out of proportion to what may be expected from so small an organ. The early symptoms may be lower abdominal or inguinal pain without scrotal signs. Later there is pain in the testicle with exquisite tenderness, edema of the scrotal tissues, and redness of the skin. The temperature is usually normal and the laboratory findings are within normal limits.

Differentiation from torsion of the spermatic cord may be impossible and for this reason early surgical exploration should be done when either condition is suspected.

The authors submit 2 case reports of torsion of the appendix testis. ROBERT O. BEADLER, M.D.

Malignant Tumors of the Testis. Treatment at Radiumhemmet Stockholm. HUGO AHLBOM. *Acta radiol. Stockh.* 1947 25: 669.

Testicular tumors differ in several respects from other tumors occurring in humans. Tumors of this type have been of considerable interest to pathologists, surgeons and radiotherapists particularly in view of their rarity.

During the latter part of the nineteenth century a period of rapid progress in tumor pathology, a favored subject for theoretical discussion and study was that of mixed or teratoid tumors of the testis. This tumor group was often used as an argument for the support of various theories pertaining to tumors in general. Ribbert and Wilms were the most important contributors to the literature on testicular tumors during this period and their conception of this tumor group and its position in the system of

factors in each case of ureteral stone is important the plan of management for each case must be individualized, in their experience ureteral catheter manipulations are superior to mechanical stone extractors, although the latter are a valuable adjunct in many instances the current trend at Cleveland Clinic in the treatment of ureteral calculi is definitely toward conservative management by manipulation rather than by open surgery

ROBERT O. BEADLEY, M.D.

GENITAL ORGANS

Safety Factors in Prostatic Surgery WILLIAM J. EWELL, *Pennsylvania M J* 94:3, 51-52.

The author states that as an indication of the degree of safety achieved in prostatic surgery we may turn to the mortality statistics. In a series of 1,997 patients there were 35 operative deaths, a mortality of 1.62 per cent. Of 1,033 transurethral resections there were 31 deaths, a mortality of 3.55 per cent. Since the safety factors of which the author speaks evolve gradually and cannot be said to apply to the entire series it seemed of interest to observe whether or not their adoption had favorably influenced the mortality rate. The cases of transurethral resection were accordingly divided into two equal periods of 8 years each one from 1931 to 1938 inclusive, the other from 1939 to 1946. During the first period 744 patients were operated upon with 25 deaths, a mortality of 3.3 per cent, while in the later period, 459 patients were operated upon with 6 deaths, a mortality of 1.3 per cent. Of the prostatectomies, 93 one-stage operations were performed with 3 deaths, a mortality of 3.15 per cent. The majority of these were performed during the second period, because the early enthusiasm of the author for transurethral resection led him to perform this operation in all cases.

Before proceeding to the contribution of the urologists to the safety of prostatic surgery there are certain other factors which should be recognized. Perhaps the greatest of these is removal of the patient's fear of both hospital and operation. It is a tribute to surgical progress in general, and to improved techniques in prostatic surgery in particular that today patients with prostatic obstruction accept recommendation for operation readily and with confidence in the successful outcome.

As a result of acceptance of operation, the patient submits to operation at an earlier stage of his disease, in better general condition, often with satisfactory renal function, and in every way a better risk.

A second factor of immeasurable value is the part played by the sulfonamides and antibiotics in the control of urinary tract infections. Alone or in combination they may be required during the preoperative preparation to combat an existing infection and may be lifesaving in the postoperative period.

The author's experience with *Bacillus coli* infections of the urinary tract has repeatedly demonstrated the great value of streptomycin which is

given at present in somewhat larger doses, starting with 4 gm. the first day decreasing the dose to 2 gm. a day and continuing this dosage until the infection is controlled.

A safety factor in prostatic surgery which is often overlooked, is the assistance of a well trained and alert house staff of resident physicians and nurses.

Many a tragedy has been averted by prompt attention to unexpected or excessive bleeding, the institution of measures to combat fall in blood pressure, the judicious and frequent administration of intravenous fluids or blood transfusion and countless other attentions which require prompt and rational action. There are few operations which require such close attention for the first 24 to 48 hours as those for prostatic obstruction, and anyone who boasts a low mortality rate owes a large debt to the hospital staff.

The surgical experience of the patient with prostatic may be divided into three phases: (1) preparation, (2) operation and (3) recovery. Of these, preparation is the most important.

A careful history and general examination of the patient has long been the accepted practice. One may however emphasize the importance of cardiovascular evaluation, and if the history is at all suggestive, an electrocardiogram and cardiac consultation are desirable. This is of importance not only in judging the operative risk but also in selecting the anesthetic agent and method.

The importance of evaluating renal function has long been recognized. It should be emphasized, however that blood chemistry studies alone are not a safe criterion for evaluating the functional status of the kidneys or for determining if and when the patient is ready for operation. Several instances could be cited in which the blood urea did not exceed normal figures and yet the urogram revealed delayed function with pronounced bilateral hydronephrosis and hydroureter a condition demanding preliminary drainage.

The procedure which, in the author's opinion, constitutes the most important and valuable single examination contributing to the safety and proper planning for the patient with prostatic disease is intravenous urography. No other single examination supplies as much information, for from it may be determined (1) renal function, (2) type of prostatic and selection of operation (3) preoperative management, and (4) estimate of risk.

The author believes that the procedure which may be relied upon to replace other tests of renal function, is that of making the x-ray exposures at 5 minute, 15 minute, 30 minute, and 1 hour intervals after the injection of diodrast. A fractional function is thus obtained. Although the interpretation of the series of urograms is only a gross method of studying renal function, it has been found to agree well with other laboratory methods.

Determination of the type of prostatic, upon which selection of operation depends, can be made from interpretation of the cystogram shadows of the series of urograms. The benign vesical neck obstructions

treatment. Practically no information regarding the prognosis was obtained from prolan tests made in 59 cases. Blood sedimentation tests seem to be of particular prognostic value in this tumor group

JOHN E. KIRKPATRICK M D

Management of Carcinoma of the Prostate. JOSEPH C. BIRDALL *J Urol* Balt., 1948, 59 320.

The incidence of carcinoma is reviewed and the figures of Young, Rich and Moore are mentioned. Young found prostatic carcinoma in 21 per cent of patients with prostatic obstruction at 292 consecutive autopsies in males over 50 years. Rich observed carcinoma in 14 per cent and Moore reported an incidence of carcinoma at autopsy in 16.7 per cent. The author has not reported cases of patients less than 44 years of age. The author states that an intelligent prostatic examination must be an essential part of every health examination in the male, to be executed at yearly intervals after the age of 40.

The diagnosis of early prostatic carcinoma is difficult, but in the author's series of 58 patients the disease arose in the posterior lobe in 90.1 per cent. The value of the Silverman biopsy needle is mentioned as an aid to early diagnosis of prostatic carcinoma and has the advantage of being an office procedure.

The value of an elevated acid phosphatase study is mentioned and particularly when sodium beta-glycerocephosphate is used as the substrate.

With regard to therapy it is pointed out that Huggins' estrogenic therapy affords a great palliative measure in inoperable prostatic carcinoma, but there has been no evidence of cure following this method of treatment. In the author's series of 15 patients who were afforded the combined therapy of orchiectomy and estrogens the longest survival period was 27 months as compared to 36.2 weeks in a group of 729 patients not so treated. The author advocates 0.05 mgm ethinyl estradiol daily for 30 days followed by a 30 day rest period before further medication.

In considering the treatment of prostatic carcinoma, the author mentions the importance of early diagnosis and radical prostatectomy. Young reported a cure in 20.6 per cent of his patients. George Gilbert Smith reported cure in 29.5 per cent and Elmer Belt reported an apparent cure in more than 50 per cent. Furthermore, Smith found that only 20 per cent of patients seen were suitable for radical prostatectomy, and Barringer saw only 5 per cent of the patients in his series early enough to permit radical surgery.

Persistent Cloaca. WILLIAM J. BAKER and J. LESTER WILKEY *J Urol* Balt. 1948 59 643

The authors report the case of a 5 year old male who entered the Cook County Hospital, Chicago, Illinois, because he voided all his urine by way of the bowels. There was no history of congenital anomalies in any other member of the family. The patient had two liquid bowel movements a day.

Fig. 1 (Baker and Wilkey). a, Shows the dilated caudal segment of the bowel the cloaca, the allantois empties into this structure. It also shows the cloacal membrane which is a thin wall of ectoderm and endoderm. b and c, In a 6 weeks embryo the urogenital septum, a frontal fold, passes downward to meet the cloacal membrane and separates the cloaca into a dorsal rectal and a ventral urogenital segment, from the dorsal surface of which the ureter stalks and wolffian ducts leave. The upper portion of this anterior or ventral segment becomes the bladder; the inferior portion becomes the posterior urethra in the male and the entire urethra in the female. d, It is believed that in this patient the urogenital septum never completely joined the cloacal membrane, which fact established a connection between the bladder and rectum, thus, a persistent cloaca is present.

The penis was very rudimentary and the testes were of normal size for a boy 5 years old. Intravenous urograms showed normal bilateral kidney function and a urinary bladder which filled with dye. Proctoscopic examination revealed a rosette of mucosa on the ventral wall just inside the anal sphincter. This was interpreted as a stoma or connection between the bladder and the rectum. It was believed that in this patient the urogenital septum never completely joined the cloacal membrane which established a connection between the bladder and the rectum. There was no evidence of a urethra, but the ureters apparently emptied into their usual location in the bladder.

Since the child was in good health in spite of the persistent cloaca and since it was doubtful whether surgery would improve that which nature had already done, it was decided not to use any operative interference in an effort to correct his defects.

JOSEPH E. MAURER M D

tumor pathology is still, for the most part, accepted by the majority of authors in this field.

In the early years of the present century Chevasu in France, and later Ewing in the United States completed the modern doctrine of testicular tumors, especially with regard to the pathogenesis, histologic classification and clinical characteristics. Chevasu gave a very good and comprehensive histologic and clinical description of these tumors. He also clearly defined the interesting and quantitatively most important subgroup and gave it the name of seminoma. He considered the origin of tumors of the testis to be the cells of the specific sex epithelium. Ewing's classification is still used by many authors, especially in America. Many pathologists and clinicians use a more or less modified Ewing classification. Ewing considered all such tumors to be mixed tumors for instance, in the case of the seminoma, the epithelial cells were supposed to have completely overgrown the other elements.

The numerous articles dealing with this subject during the last 30 years have added to our knowledge in two ways. First the methods of treatment—surgical as well as radiological—have been gradually improved and the late results have been correspondingly more satisfactory. Secondly the investigations about hormonal excretion in cases of tumors of the testis (Zondek since 1929 and others) have opened a new field of research. At least, according to some authors (Ferguson, Bang, Hamburger and Nielsen and others) the last mentioned research work has already led to practical results, particularly as an aid in the evaluation of the prognosis and the therapeutic results.

Besides the special features mentioned (concerning pathology and endocrinology) the following clinical characters are of particular interest:

1. The average age of the patients is unusually low. Most authors agree that practically all patients are within the age group of 20 to 30 years.

2. Trauma as an etiologic or predisposing factor has been considered by several authors of more importance in tumors of the testis than in most other types of tumor. The frequency of trauma in the author's material was 5 per cent. Trauma to the testes is not at all unusual and, being rather painful, is not so easily forgotten by the patients, even if relatively slight. The frequency of trauma among patients with testicular tumor does not seem to be high enough to be anything but incidental.

3. Retention of the testicle is a definite statistically proved predisposing factor. According to Grevillius, who made a survey of the contributions to this question in the literature tumors occur 40 times more frequently in abnormally than in normally situated testicles. The average frequency of testicular retention in the published series by Grevillius was found to be 13 per cent. Exactly that frequency was also found in the author's material. In both series, cryptorchism was relatively more frequent in the seminoma subgroup than in other types of tumor.

4. Gynecomastia in general is a relatively rare condition. It is seen mostly during and soon after puberty and often as a one-sided hyperplasia. In the form of ductal fibroadenomatosis it also occurs in men of relatively advanced age (50 to 60 years), sometimes bilaterally. In the last mentioned cases the condition must be considered as a precancerous one. Among male patients, gynecomastia is otherwise seen only in those with tumors of the testis and in those with carcinoma of the prostate who have been treated with female hormones over a long period of time.

5. The radiosensitivity of the seminomas is considered to be high by all authors of recent papers. The other microscopical types of tumors of the testis, on the other hand, are usually said to be only slightly radiosensitive.

6. Metastases of malignant tumors occur (if the patient is not cured at an early stage) in the upper para-aortic lymph nodes, the typical "first station," and in the left supraclavicular lymph nodes. Metastases in lungs, pleura, mediastinal lymph nodes, skeletal system etc. were found only in rare cases, on clinical examination.

Inguinal metastases, also are rare a fact which seems to be much better known now than it was 10-15 years ago, when patients were sometimes seen who had received inguinal irradiation only after orchiectomy.

Among the numerous methods of treatment described in the literature three main principles may be distinguished:

1. Radical surgery including removal of the retroperitoneal lymph nodes. This difficult operation has been worked out by Chevasu and Ilmman and is in use at a few clinics, probably only for the less radiosensitive tumor types. The radical operation is sometimes combined with postoperative roentgen treatment.

2. Simple orchiectomy usually followed by roentgen irradiation. This method seems to be favored by the majority of recent authors, especially in cases of seminoma.

3. Primary irradiation either routinely as a pre-operative treatment followed later by orchiectomy or in the case of radiosensitive tumors, without surgical intervention.

At Radiumhemmet the principle of orchiectomy followed by roentgen treatment of the upper para-aortic lymph nodes has always been applied.

From 1922 to 1941 inclusive, 119 patients with malignant tumors of the testis were treated. The 5 year cures for the whole series amounted to about 50 per cent for those without metastases about 70 per cent. Of those with seminomas, 65 patients (65%) had 5 year cures, and among those with adenocarcinomas and malignant mixed tumors, 44 patients (35%) had 5 year cures. Among those with seminomas without metastases, the 5 year cure rate was about 80 per cent. Orchiectomy and postoperative roentgen treatment, chiefly on the para-aortic lymph nodes, is considered the best method of

GENTOURINARY SURGERY

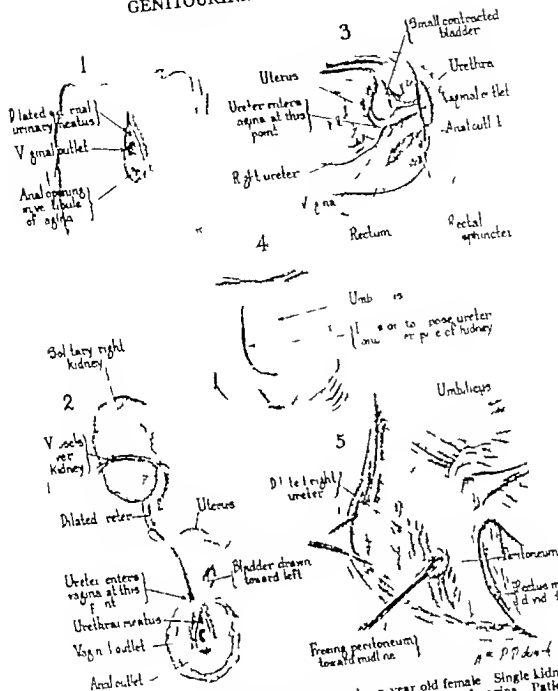

Fig. 3. Case 3 (Lowrey). Congenital anomaly 7 year old female. Single kidney (right) with ureter opening into vagina. rectal outlet in vestibule of vagina. Patient had fecal control but urinary incontinence. 1 View of dilated urethral meatus, vaginal outlet and anal opening in vestibule. 2 Reconstruction of condition found at operation. Solitary (right) kidney with dilated ureter opening into vagina. 3 Sagittal view showing insertion of ureter into vagina and position of rectal outlet in vestibule. Rectal sphincter muscles present in normal position. 4 Skin incision to expose ureter and lower pole of kidney. 5 Exposing dilated ureter.

but the ureter from the patient a single (right) kidney was aberrant, opening into the wall of the vagina, and was incontinent and hence she was constantly wet.

The condition prior to operation and the operation are well illustrated in this article.

In conclusion the author believes that extensive surgical procedures necessary to accomplish correction of a persistent cloaca were justified because of the psychological changes that took place following

correction of this anomaly. These patients can be rehabilitated and surgery should be done before the child reaches school age. CONRAD A. KUENZ M.D.

Wartime Injuries of the Urinary Tract D. S. POOLE WILSON RICHARD MOGO, and GEOFFREY PARKER. *Brit J Urol.* 1947 19 190.

A total of 81 patients were seen at a British genitourinary center during the war. Almost invariably suprapubic cystostomy was done. In relatively few

Rectum opened into vaginal vestibule (cloacal pouch) which was covered at birth in apron of tissue opened by obstetrician. With tabounds through which urine and feces passed. Condition present apron of tissue covers urethral, vaginal and rectal outlets. Skin incision to expose portion of rectum and make new anus. Freeing rectum. 2 Sagittal view of condition present.

Perastent Cloaca. OSWALD S. LO SLRY J. Lral
Balt. 948 39: 69

Persistent cloaca in the human is probably the rarest of all developmental defects. Only 5 cases in which the treatment was surgical have been reported in the literature. The author reports 3 cases of persistent cloaca in young females (one 9 years of age and the other 7 years of age) in whom the condition was corrected by operation.

The human embryo passes through a period during which, like birds and reptiles, it has a common cloaca for both feces and urinary excretion. It seems

strange to the author that persistent cloaca was not found more often. The cases described were true cloacas because both feces and urine emptied into cloacal type of pouch and emanated from this pouch through the same aperture.

In the first case both ureters emptied into a continent bladder but there was overflow incontinence as the bladder was absolutely untrained and without sensation. The rectum opened into the vestibule of the vagina (cloacal pouch).

In the second case the rectum opened into the lower part of the vaginal vestibule and was continent

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES TENDONS ETC.

Trauma to the Region of the Bursa Anserina
CHARLES J. SUTRO *Am J Surg* 1948 75 489.

The bursa anserina is located superficially to the usual collateral ligament on the upper medial surface of the tibia. The bursa is enclosed by the tendons of the sartorius gracilis and semitendinosus.

The observations of the author were based on a study of 3 soldiers who had suffered injuries from the hoof of an animal while participating in military training. Persistent local pain and swelling were present along the inner aspect of the proximal portion of the leg the pain over this area was severe when the leg was fully flexed against active resistance.

In 2 cases treatment consisted of hospitalization with bed rest, and warm or cold compresses whirl pool baths infrared irradiation and nonweight bearing quadriceps exercises gave relief. The third patient, who was seen 44 days after injury had a swelling the size of a small lemon. He did not respond to conservative treatment. Exploration revealed that the mass consisted of a subcutaneous adventitious bursa which had a direct channel to the cavity of the contiguous bursa anserina.

DANIEL H. LEVINTHAL, M.D.

Concerning the Pathology and Treatment of Tennis Elbow
J. R. S. LAMB *Med J Australia* 1947 2 737

Following a detailed review of anatomical considerations in the disability described as tennis elbow the author presents his view of the pathologic changes. A painful localized synovial reaction occurs as the result of either direct trauma or trauma due to muscle play. This reaction may be acute and stormy, but in many cases it passes on to a chronic stage of inflammation. The neighboring capsule and muscles, which are the original cause become secondarily involved and in rare cases, the perosteum. As in synovitis of the knee, adhesions in the synovial membrane may eventually form and fibrosis may occur in the muscles. Unresolved, inflamed and persistently irritated membranes may undergo patchy thickening. This thickening probably accounts for the occasional click felt when the radius is rotated and flexed. In view of the presence of such chronic inflammation in the near neighborhood of the periosteum occasional paraepicondylar ossification is not surprising.

Avoidance of the provocative cause for some weeks often effects a cure in the milder cases. In the more pronounced lesions immobilization in a plaster spica including the wrist and elbow with the elbow almost fully extended is indicated. The wrist is cocked up and the fingers are left free. In less acute cases a hand and finger platform splint is used—the wrist

with the semiflexed fingers being cocked up and the elbow being kept flexed in a sling. A strong sedative is indicated in the fulminating cases. Three weeks rest in spica or splint is followed by 1 week in a simple wrist cock up splint. This treatment seldom fails to produce a cure or to benefit the patient greatly. During the splint or plaster treatment, prophylactic shoulder and finger exercises should be carried out.

In chronic cases manipulation is worth trying. Manipulation is ill-advised if the disease is acute and in any case cannot be expected to effect a cure unless adhesions are present.

While injection treatment with a local anesthetic agent has had quite a vogue, the author does not consider it favorably.

Deep roentgen therapy is strongly recommended, especially in Germany theoretically this method of treatment should hold out some hope of success and warrants a wider trial.

If conservative treatment fails operative attack is well worth while in the small percentage of patients needing such operation.

The aim of operation should be to treat the underlying abnormality. The author prefers arthrotomy for which the elbow should be kept flexed and the forearm supinated for in this position the radiohumeral joint is most easily inspected. The tendon is exposed then keeping medial to the base of the epicondyle, the surgeon makes a slightly oblique cut towards the joint. With a blunt dissector the synovial pouch is pushed away from the epicondylar region toward the center of the joint. Synovial tags or thickening are removed a special search for these being made in the epicondylar region and in the line of the radiocapitular joint. Meniscuslike projections are excised. In the author's cases, two chromicized sutures were used in the superficial part of the musculotendinous mass and the deep part was left gaping. The synovial membrane is not sutured.

The elbow is then encased in a plaster spica for 1 week after which gradually increasing exercises are taken with intermittent use of a sling.

In all cases cure has been immediate. Once cured, tennis elbow rarely recurs. Successful operations have the common factor of easing tension in the radiohumeral joint.

RUDOLPH S. REICHT, M.D.

Lesions of Vertebral Bodies. JOSE VALLS, CARLOS E. OTTOLENGHI, and FRITZ SCHAPOWITZ. *J Am Med Ass.*, 1948, 136 376.

The authors describe the equipment and technique required for aspiration biopsies of the vertebral bodies, the indications for and the end results obtained with the use of the method in 86 cases.

A long double needle, somewhat similar to a spinal tap needle, is employed, and a guide is used to aid in the proper placement of the needle. Not all parts of the spine are accessible to puncture. The

cases was any attempt made at the primary operation to repair the urethra, other than the use of an indwelling catheter in cases of injury to the posterior urethra. The removal of foreign bodies, if present and the delayed suture of perineal wounds was carried out. When the urethra was completely ruptured repair was accomplished. The results were deemed satisfactory. Penicillin was used both intramuscularly and by local and urethral irrigation. The author states that in ideal surroundings one should often perform suprapubic cystostomy and a complete repair of the urethra at the primary operation, but that delayed suture of the urethral wound has been proved to give satisfactory results. In cases of complete rupture of the posterior urethra however alignment should be restored and maintained by means of an indwelling catheter at as early a time as possible.

The incidence of wartime bladder injuries was not more than 1 in 3,000 or 4,000. Two main groups of bladder injuries exist: (1) rupture due to sudden increase of internal hydrostatic pressure and (2) puncture of the bladder by foreign body or adjacent bone. The most important factor in the treatment of any bladder wound was the prevention of perivesical cellulitis which was achieved ideally by immediate su-

ture of the wound of the bladder wall and drainage of the perivesical cellular tissue. Suprapubic cystostomy was done. Perforation of the bladder per se usually caused comparatively little shock. Leakage of urine from the external wound was common but not invariable and if the diagnosis was in doubt, cystograms were made.

Of the 17 patients with renal injury it was found possible to preserve and repair the kidney in 9. The lacerations in the renal parenchyma were repaired with ordinary interrupted sutures of plain No. 1 catgut with strips of muscle interposed. When the renal pedicle was injured, light pressure by means of a rubber-covered clamp was applied to control the hemorrhage, while a careful dissection was performed. Often only one of the branches of the main vessel was involved, and a major portion of the kidney could be preserved.

Complete section of the lower ureter was considered best treated by reimplantation into the bladder when seen late. If this could not be done without tension then a flap of bladder could be turned up, fashioned into a sleeve and joined to the cut end of the ureter. For the upper lengths of the ureter transplantation into the colon was advised before resorting to nephrectomy. JOSEPH E. M. RICE, M.D.

tures passed through it and the drill holes in the humerus. The sacs chosen for use in these cases were from chronic or recurrent hydroceles and had walls one-eighth of an inch thick. Presumably a chronic hernial sac would answer just as well.

No sepsis followed the operations (performed in 1944) and 6 months after operation the joints had about 60 per cent of normal flexion extension and rotation movements without pain with no instability whatever and with considerable power.

The following points in technique call for emphasis (1) careful asepsis is essential (2) the extent and method of bone resection give the new joint excellent stability (3) preservation of the attachments of the triceps and brachialis tendons gives one a long handicap in the early recovery of active muscular control of movement and (4) it is surmised that a peritoneal graft into a joint may be an adequate substitute for a lost synovial membrane.

RUDOLPH S. REICH M.D.

The Treatment of Dropped Shoulder A New Operative Technique. *EXNER SPIRA, J Bone Surg 1948 30-A 229*

The author believes that in some cases of severe paralysis of the shoulder and shoulder girdle muscles it is sometimes necessary to fix the scapula to the thorax. He has used three methods

1. Wiring of the scapula to the ribs. This has failed.
2. The lower end of the scapula is notched so as to fit over the rib at the proper level (in one case the sixth).
3. A hole is fashioned near the lower tip of the scapula and after a rib is divided and freed it is passed through this hole and the rib ends are re-fastened.

The last method only afforded rigid fixation.

The cases under treatment were complicated by a lack of control of the head. In both of them the chin lay on the chest and in the one the head deviated to the side. In both cases satisfactory control of the head developed after scapular fixation.

NEWTON C. MEAD M.D.

Experience and Results from Mobilizing Plastic Operations in 4 Cases of Osseous Ankylosis of the Knee. *H. STÖCKM Acta orthop scand., 1947 17 146*

Stability is very important to knee joint function and this is normally maintained by the ligaments and fibrous capsule. These soft tissues are usually destroyed by diseases or injuries which lead to bony ankylosis. Restoration of useful, painless motion without loss of stability is difficult, but the author believes the advantages of motion often justify the operation.

The function of the quadriceps is essential to a good result. An ankylosed patella offers a less favorable prognosis but does not contraindicate the operation. The technique of arthroplasty is as follows.

An anterior S shaped or Payr incision is used. The joint space is made largely at the expense of the

femoral condyles, so that with light traction one centimeter of space is present. The condyles are bevelled posteriorly so that very little of the posterior portion remains. A coherent fat flap from the abdomen is placed between the bony surfaces. In the 2 last cases Hasse's method of leaving a high intercondylar eminence was followed.

Postoperatively skeletal traction via the os calcis is applied with the knee flexed from 10 to 40 degrees over a Braun splint. Passive exercise is begun on the tenth day by having the patient move the pelvis up and down. On the twentieth day the leg is permitted to hang. The traction wires are not removed until the fifth week. The patient is allowed up in from 6 to 8 weeks.

In the 4 cases reported a useful knee resulted from this operation. Satisfactory flexion with weight bearing was obtained and complete or almost complete extension was present.

Some instability pain on prolonged use, and crepitus were among the residual postoperative effects. The late roentgenograms show extensive degenerative changes in these joints, but pain free motion was present and could not be correlated with the roentgenographic appearance. The one patient who was reoperated upon following a poor result from arthroplasty with fascia lata over the bone surfaces showed that coalescence of the capsule and the thick layer of connective tissue which covered the tibia were the cause of stiffening after the first operation.

NEWTON C. MEAD M.D.

Fusion Operation for Bone and Joint Tuberculosis Associated with Multiple Tuberculous Foci. *EMIL D. W. HAEGER, Q Bull Northwest Univ M School 1948 22 38*

A series of 5 cases of multiple tuberculous infection with bone and joint foci is presented. The usual locations of the nonosseous tuberculosis were the lungs and the urinary tract. It was formerly a generally accepted principle that surgery of the bones and joints was contraindicated in cases of multiple tuberculous lesions. However with good preoperative care and long periods of convalescence it was possible to cure the osseous lesions by obtaining solid operative fusions of the affected joints which aided in the rehabilitation of the patient.

The author believes that the success of his treatment is related to the fact that all patients are treated on the basis that tuberculosis is a generalized disease.

VERNON C. TURNER M.D.

Conservative Surgery in Tumors of Bone with Special Reference to Segmental Resection. *BRADLEY L. COLEY and NORMAN L. HIGGINBOTHAM, Ann. Surg 1948 127 231*

The authors report 3 cases of tumors of the bone in patients who were treated by segmental resection and massive bone grafts. In 2 patients the middle third of the humerus was involved in 1 patient the middle third of the ulna was involved. In 1 case the tumor was a thrice recurrent central chondroma. In a

first three cervical vertebrae can be approached by the pharyngeal route the fourth, fifth, sixth, and seventh cervical vertebrae are accessible laterally. The posterior border of the sternocleidomastoid muscle is used as a guide to determine how far laterally to place the needle. The muscle must be kept anterior to the needle in order to protect the cervical vessels and nerves. Even if the finer inner needle punctures a vessel or organ such as the esophagus, the authors believe that little harm results, and they point to the great number of sympathetic blocks that have been performed without untoward effect. It is recommended that needle biopsy should not be attempted in the first 9 thoracic vertebrae which are in intimate contact with the descending aorta, the vena cava, the esophagus, and the thoracic duct. The tenth, eleventh, and twelfth thoracic vertebrae and the lumbar vertebrae are readily reached although it is apparent that one must follow quite accurately the technique described. The needle direction and position must always be checked by roentgen examination in two planes, prior to final placement.

Of the 86 patients on whom the procedure was performed it was possible to determine accurately the nature of the lesion in 59 (69%).

VERNON C. TURNER, M.D.

Some Cases of Paravertebral Defects in the Anterior Portion of the Vertebral Body with Remarks on the Pathogenesis of the Lesions in Question
ARVID HELLSTADT. *Acta orthop scand* 947 7 50.

Eight cases showing a variety of defects of the anterior portions of the vertebral bodies adjacent to the intervertebral discs are presented and discussed. These cases include lesions similar to Schmorl's nodes, lesions presented by Scheuermann's disease and to so-called "persistent apophyses."

The author points out that these lesions are not due to tuberculosis or sepsis, despite the fact that there is often narrowing of the intervertebral cartilage. He does not consider them Schmorl's nodes because they are too anterior to be due to herniation of the nucleus pulposus; however he does believe that many of them represent compression and fracture of the vertebral body with displacement of the annulus fibrosus into the defect. This may be either a sudden process as the result of severe trauma, or it may be a gradual invasion of the vertebral body through a small traumatic defect or through vascular channels.

The author believes that the "persisting apophyses" are due also to the impaction of disc tissue and that this impaction is also important in the production of the defects seen in Scheuermann's disease.

The treatment depends on the severity of the symptoms. It varies from complete bed rest in the severe cases, to simple rest and physical therapy. Use is made of plaster casts and cloth corsets. Spinal fusion is sometimes indicated.

NEWTON C. MEAD, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Transplantation of the Extensor Carpi Ulnaris to Give Abduction of the Thumb. MICHAEL BEN-MAIM. *N York State J M* 915, 48, 383.

The author has devised an operation in which the tendon of the extensor carpi ulnaris is transplanted through the sheath of the abductor pollicis longus to give abduction of the thumb. The abductor motivates the withdrawal of the thumb from the palm to allow grasping, and the replacement stabilizes the base of the thumb to give better opposition.

The first incision, which is 1 inch long with the base of the first metacarpal at its center, exposes the long abductor tendon at its insertion. The second incision is over the distal two-thirds of the muscle and tendon of the extensor carpi ulnaris, extending proximally from the base of the fifth metacarpal. The tendon is freed, inserted, and passed through subcutaneous tunnel to appear in the first wound. Care is taken to free sufficient length of tendon and muscle so that the muscle may function freely in its new location. The tendon is passed without twisting and is anchored under neutral tension beneath a bone flap in the base of the first metacarpal bone, the thumb being held in wide abduction in the plane of the hand. The thumb is immobilized in abduction with plaster for 3 weeks before muscle re-education is started.

The operation is recommended particularly for the spastic hand in which the thumb lies across the palm due either to paralysis or stretching of the abductor pollicis longus. A stripping of the contracted thenar muscles or abductor action should be done at the same time. It is also recommended for some cases of postpoliomyelitis hand involvement and in some cases of Erb's brachial birth palsy. In the latter two conditions other operations, such as wrist fusion are usually indicated also.

VERNON C. TURNER, M.D.

A Technique for Arthroplasty of the Elbow Joint.
A. CAMERON ARMSTRONG. *Med J Australia*, 1947 2 76.

The author describes the technique employed in operations on a young soldier whose elbow was ankylosed as a result of war wounds.

The head and neck of the radius are removed the anterior and posterior surfaces of the articular portion of the humerus are removed by osteotomy in such a way as to leave them flush with the flat surface of the humerus just above the fossae. The concave articular surface of the ulna is enlarged with a bone gouge, care being taken to preserve the insertions of triceps and brachialis tendons, three or four small drill holes are made through the lower end of the humerus in a horizontal line, about one inch from the end. The sac of a moderate sized hydrocele is drawn over the lower end of the humerus like a cap, with its peritoneal surface outermost. It is then firmly sutured into place with chromicized gut suture.

circumstances the impact is innocuous. However when the natural forces such as winds and terrain are adverse the jumper may experience an intolerable dissipation of the stress and a variety of injuries may be sustained. Such injuries may involve the crushing or torsion of the metatarsal bones or the driving of the talus into the mortise posteriorly fracture of the posterior tibial margin rupture of the tibiofibular ligament or spiral fracture of the tibial and fibular shafts.

External rotation injuries. Two-thirds of all fractured ankles in the present studies were found in the distal end of the fibula. The fractures were oblique in nature and were acquired by external rotation of the limb. The mechanism of this injury is similar to that postulated by Ashhurst and Bromer. Since the lesion is produced by external rotation the treatment consists of slight internal rotation until healing is assured. Widening of the mortise is a well known sequel during the period of convalescence. To avert diastasis in this type of fracture the writers recommend vigilance plus extension of immobilization to the upper end of the thigh. Other external torsion injuries include the medial malleolus ligaments namely the deltoid and the inferior tibiofibular ligament. The latter when traumatized invariably jeopardizes the integrity of the ankle mortise and should be recognized and treated. Spiral fractures of the tibia and fibula at different levels are symbolic of external rotation injuries. The former occur at the juncture of the middle and lower thirds of the tibia and the latter at the upper third of the fibula. Meniscal and ligamentous injuries of the knee joint are also commonly observed. However as a rule derangement of the knee joint is of the abduction type of injury.

Landing-thrust injuries. These are usually associated with dorsal dislocation of the big toe fractured sesamoid impaction of the metatarsals, crushing of the metatarsal bones and soft tissue injuries.

In the event that the metatarsal bones are spared the posterior tibial margin may not escape fracture. Solitary fracture of this bone was originally described in 1909 by Meissner rediscovered by Cotton in 1915 and again rechristened during the last war as the paratrooper fracture.

Injuries of external rotation plus landing thrust. The usual pattern involved is one of fractured lateral malleolus and posterior margin and bimalleolar fracture with fracture of the posterior tibial margin which may be complicated by posterior dislocation of the foot and postreduction arthritic manifestations. The disability must be dealt with in such a way as to preserve the mortise. Open reduction of the posterior tip with internal fixation of the medial malleolar fracture is often mandatory.

Adduction and internal rotation produces 'sprained ankle' which may include disruption of the fibulocalcaneal ligament or avulsion fracture of the fibula. It may also produce fracture of the fibula at the level of the ankle joint and vertical split of the tibial malleolus.

Backward landing. Vertebral fractures and cranio-cerebral injuries characterize this mechanism of injury. Most fractures involving the vertebrae are of the compression type. The thoracolumbar region is the site of predilection. Anterior collapse of the involved vertebrae is the usual pattern. Violent hyperflexion of the spine when the paratrooper strikes the ground on his buttocks is responsible for the bony disintegration. Equally devastating is the soft tissue injury incurred upon the tendinomuscular apparatus of the spine i.e. low back sprains herniated intervertebral discs contusions of the coccyx, and traumatic myositis. The authors assert that there were 10 soft tissue injuries to one compression fracture of the spine. In their experience the trivial spinal injuries caused more notoriously disqualifying sequelae than the frank compression fractures.

Opening shock. Injuries acquired by this means occur in the midair or prior to ground contact on the part of the jumper. They are of two general types.

1. Whiplike in which the jumper is out of line with the tug of the opening parachute flipping him upside down. Sprained neck, transient neuropathies of the brachial plexus and ecchymotic brush burns may result.

2. In suspension line injuries extremities may become entangled with suspension lines prior to the unfurling of the parachute. Sudden arrest of gravitational descent exacts a toll of 40 per cent fractured femurs and more than $\frac{1}{4}$ of all fractured humeri in midair. More common is the tear of the medial collateral and cruciate ligaments of the knee. Dislocation of the shoulders (10 cases) diastasis of the pubic symphysis (3 cases) and laceration of the perineum including the rectum, are some of the remaining bizarre occupational complexities of a paratrooper.

SAMUEL L. GOVERNALL, M.D.

Slipped Femoral Epiphysis. ARMIN KLEIN, ROBERT J. JOPLIN and JOHN A. REIDY. *J. Am. M. Ass.* 1948 136:445

The treatment of slipped capital femoral epiphysis at the Massachusetts General Hospital Boston has been standardized. Patients with pronounced slipping of the epiphysis have been treated by arthrotomy reposition of the displaced epiphysis on the neck of the femur and fixation by means of a three flanged nail. Patients with only minimal slipping have been treated by lateral nailing *in situ* without arthrotomy and without correction of the early deformity. Patients with an acute slipping or what may be termed an epiphyseal fracture, are treated by manipulation, cautiously slow and extremely gentle and nailing with the three flanged nail. If complete reduction as determined by anteroposterior and lateral roentgenograms of the hip cannot be obtained by gentle manipulation open reduction is accomplished and the position is maintained by nail.

The degree of slipping of the epiphysis is determined by the distance that the head has slipped from the superior outline of the femoral neck as seen in the lateral view of the hip. If this distance is 1 cm.

patient who had remained well for a period of 12 years in the second case the growth was a twice recurrent fibrous dysplasia. In the third case the lesion was a fibrosarcoma of low grade malignancy.

Tumors of the scapula, patella or clavicle may be treated by total extirpation. The authors state that conservative surgery for tumors of the bone may be substituted for amputation in selected cases. If amputation is unavoidable it should be done at the lowest level compatible with safety.

Curettage, partial resection, segmental resection, and excision are methods which may at times be used in lieu of amputation. Certain histologic types and certain clinical and roentgenographic settings indicate the advisability or the inadvisability of attempting conservative measures of treatment.

High amputation of the thigh for osteogenic tumors and chondrosarcoma of the lower femur may in selected cases be a safe substitute for disarticulation of the hip and offers greater advantages to the patients who survive.

The authors report 24 additional cases of tumors of bone. Several methods of treatment were employed viz. local resection, curettage and bone grafting or complete excision of the involved bone.

FRACTURES AND DISLOCATIONS

Experimental Study of Fracture Sites (Internal Contact Spillat). WILLIAM H. ANDERSON and NORMAN E. WRIGHT. *J Bone Surg* 9:2, 30-A-43.

Three groups of animals were subjected under anesthesia to fracture of the femora in the following manner:

In the first group a simple fracture was produced and the animals were sacrificed on the second, fifth, seventh, fifteenth, and twenty-first days.

The second group of animals were subjected to a similar fracture but it was immediately converted to a compound fracture and exposed to the air.

In the third group in addition to subjecting the animal to simple and compound fractures the ends of the bones were severely traumatized by 10 blows.

All specimens were decalcified and studied. The picture presented was comparable to that previously reported by Ham and others i.e. numerous lacunae which normally house the mature adult bone cell were found to be devoid of cellular content. Further more the lining of the haversian canals had undergone marked destruction of endosteum and the capillary network. Evidence was obvious that trauma involved not only death of the bone cell, but a vascular catastrophe as well. When the microscopic slide was moved away from the cortex general cellular necrosis of the cortical bone was found up to the medullary canal. The first evidence of living tissue was observed in the haversian canals near the marrow cavity. Cellular death was not conspicuous in the medullary portion near or at the site of fracture. On the other hand a preponderance of cellular disintegration was noted on the cortex at the same level of

the medullary cavity which failed to show cell death. Hence medullary bone is less vulnerable than cortical bone.

The experimental simple fracture showed the least cortical devitalization. Conversely, those animals whose fractures were compounded manifested a wider zone of cortical devitalization than those with simple fractures. In the third group of dogs in which the ends of the bone were severely traumatized, a greater destruction of bones was observed than in the former groups.

Obviously the inference of the author's experimental data clearly indicates that severely traumatized ends of bones share equally in the devitalization and should be removed before internal fixation is completed. The removal of this nonviable tissue enhances the normal physiology of bone repair and union.

The Mechanism of Injury and the Distribution of 3,000 Fractures and Dislocations Caused by Parachute Jumping. ROY CECRORE and ROBERT M. RICHMAN. *J Bone Surg* 9:2, 30-A-77.

An extensive study on parachute injuries was conducted at the Airborne School at Ft Benning, Georgia. The report assumes definitive entities relative to mechanism, and anatomical/morphologic aspects of parachute injuries encountered among 3,000 major accidents which were categorically assessed and treated in a fracture center. Some of the major injuries were fractures, dislocations, sprains, contusions, and numerous lesser soft tissue lesions sustained either in midair or when parachutists struck the ground (landing thrust).

Ninety per cent of the injuries involved the eight bearing organs of locomotion, being fractures of the foot, ankle, leg, femur and spine, respectively. The traumatic hazards show a demonstrable predilection for the lower extremity. Eighty per cent or 2,334 of the soldiers sustained fractures from the tip of toes to and including the patella. The ankle per se, absorbs 50 per cent of the total number of cases. This is obvious as the men are instructed to land on their feet first. According to the momentum, air current oscillations, and uneven terrain, the parachutist absorbs the majority of the effects of the landing thrust on his ankles.

Cerebral concussions were noted in 110 patients in the present studies. These were due to a backward fall and occurred despite the adequate head protection worn by soldiers.

The authors list and discuss 4 traumatic etiological mechanisms which by and large affect the most vulnerable parts of the parachute jumper: they are (1) torsion plus landing thrust, (2) backward landing, (3) opening shock, and (4) vertical fall.

Torsion plus landing thrust. The parachutist descends with a downward and forward momentum, both gravity and wind drift governing the vertical and horizontal components. At the time he strikes the ground he meets an upward and backward reactive thrust or "landing thrust." Under ideal cir-

circumstances, the impact is innocuous. However when the natural forces such as winds and terrain are adverse the jumper may experience an intolerable dissipation of the stress and a variety of injuries may be sustained. Such injuries may involve the crushing or torsion of the metatarsal bones or the driving of the talus into the mortise posteriorly fracture of the posterior tibial margin rupture of the tibiofibular ligament or spiral fracture of the tibial and fibular shafts.

External rotation injuries Two-thirds of all fractured ankles in the present studies were found in the distal end of the fibula the fractures were oblique in nature and were acquired by external rotation of the limb. The mechanism of this injury is similar to that postulated by Ashhurst and Bromer. Since the lesion is produced by external rotation until healing is assured Widening of the mortise is a well known sequel during the period of convalescence. To avert diastasis in this type of fracture the writers recommend vigilance plus extension of immobilization to the upper end of the thigh. Other external torsion injuries include the medial malleolus ligaments namely the deltoid and the inferior tibiofibular ligament. The latter when traumatized invariably jeopardizes the integrity of the ankle mortise and should be recognized and treated. Spiral fractures of the tibia and fibula at different levels are symbolic of external rotation injuries. The former occur at the juncture of the middle and lower thirds of the tibia and the latter at the upper third of the fibula. Meniscal and ligamentous injuries of the knee joint are also commonly observed. However as a rule derangement of the knee joint is of the abduction type of injury.

Landing-thrust injuries These are usually associated with dorsal dislocation of the big toe fractured sesamoid impaction of the metatarsals, crushing of the metatarsal bones and soft tissue injuries.

In the event that the metatarsal bones are spared the posterior tibial margin may not escape fracture. Solitary fracture of this bone was originally described in 1909 by Meissner rediscovered by Cotton in 1915 and again rechristened during the last war as the paratrooper fracture.

Injuries of external rotation plus landing thrust The usual pattern involved is one of fractured lateral malleolus and posterior margin and bimalleolar fracture with fracture of the posterior tibial margin which may be complicated by posterior dislocation of the foot and postreduction arthritic manifestations. The disability must be dealt with in such a way as to preserve the mortise. Open reduction of the posterior tip with internal fixation of the medial malleolar fracture is often mandatory.

Adduction and internal rotation produces sprained ankle which may include disruption of the fibulocalcaneal ligament or avulsion fracture of the fibula. It may also produce fracture of the fibula at the level of the ankle joint and vertical split of the tibial malleolus.

Backward landing Vertebral fractures and cranio-cerebral injuries characterize this mechanism of injury. Most fractures involving the vertebrae are of the compression type. The thoracolumbar region is the site of predilection. Anterior collapse of the involved vertebrae is the usual pattern. Violent hyperflexion of the spine when the paratrooper strikes the ground on his buttocks is responsible for the bony disintegration. Equally devastating is the soft tissue injury incurred upon the tendinomuscular apparatus of the spine, i.e., low back sprains herniated intervertebral discs contusions of the coccyx and traumatic myositis. The authors assert that there were no soft tissue injuries to one compression fracture of the spine. In their experience the trivial spinal injuries caused more notoriously disqualifying sequelae than the frank compression fractures.

Opening shock Injuries acquired by this means occur in the midair or prior to ground contact on the part of the jumper. They are of two general types:

1. Whiplike in which the jumper is out of line with the tug of the opening parachute flipping him upside down. Sprained neck, transient neuropathies of the brachial plexus, and ecchymotic brush burns may result.

2. In suspension line injuries extremities may become entangled with suspension lines prior to the unfolding of the parachute. Sudden arrest of gravitational descent exacts a toll of 40 per cent fractured femurs and more than 1/4 of all fractured humeri in midair. More common is the tear of the medial collateral and cruciate ligaments of the knee. Dislocation of the shoulders (10 cases) diastasis of the pubic symphysis (3 cases) and laceration of the perineum including the rectum are some of the remaining bizarre occupational complexities of a paratrooper.

Slipped Femoral Epiphysis. ARMIN KLEIN, ROBERT J. JORLIN and JOHN A. REIDY *J Am M Assoc*, 1948 130 445

The treatment of slipped capital femoral epiphysis at the Massachusetts General Hospital, Boston, has been standardized. Patients with pronounced slipping of the epiphysis have been treated by arthrotomy reposition of the displaced epiphysis on the neck of the femur and fixation by means of a three flanged nail. Patients with only minimal slipping have been treated by lateral nailing *in situ* without arthrotomy and without correction of the early deformity. Patients with an acute slipping or what may be termed an epiphyseal fracture are treated by manipulation cautiously slow and extremely gentle, and nailing with the three flanged nail. If complete reduction as determined by anteroposterior and lateral roentgenograms of the hip cannot be obtained by gentle manipulation, open reduction is accomplished and the position is maintained by nail.

The degree of slipping of the epiphysis is determined by the distance that the head has slipped from the superior outline of the femoral neck, as seen in the lateral view of the hip. If this distance is 1 cm.

patient who had remained well for a period of 12 years in the second case the growth was a twice recurrent fibrous dysplasia. In the third case the lesion was a fibrosarcoma of low grade malignancy.

Tumors of the scapula, patella, or clavicle may be treated by total extirpation. The authors state that conservative surgery for tumors of the bone may be substituted for amputation in selected cases. If amputation is unavoidable it should be done at the lowest level compatible with safety.

Curettage, partial resection, segmental resection, and excision are methods which may at times be used in lieu of amputation. Certain histologic types and certain clinical and roentgenographic settings indicate the advisability or the inadvisability of attempting conservative measures of treatment.

High amputation of the thigh for osteogenic sarcoma and chondrosarcoma of the lower femur may in selected cases, be a safe substitute for disarticulation of the hip and offers greater advantages to the patients who survive.

The authors report 14 additional cases of tumors of bone. Several methods of treatment were employed viz. local resection, curettage and bone grafting or complete excision of the involved bone.

More common is the tear of the medial collateral and cruciate ligaments of the knee. Dislocation of the shoulders (10 cases) diastasis of the pubic symphysis (3 cases) and laceration of the perineum including the rectum are some of the remaining bizarre occupational complexities of a paratrooper.

SAMUEL L. GOVERNALL, M.D.

Slipped Femoral Epiphysis. ARMIN KLEIN, ROBERT J. JOYLM and JOHN A. REIDY *J Am M Ass.*, 1948 136 445

The treatment of slipped capital femoral epiphysis at the Massachusetts General Hospital Boston has been standardized. Patients with pronounced slipping of the epiphysis have been treated by arthrotomy reposition of the displaced epiphysis on the neck of the femur and fixation by means of a three flanged nail. Patients with only minimal slipping have been treated by lateral nailing *in situ* without arthrotomy and without correction of the early deformity. Patients with an acute slipping or what may be termed an epiphyseal fracture, are treated by manipulation cautiously slow and extremely gentle and nailing with the three flanged nail. If complete reduction as determined by anteroposterior and lateral roentgenograms of the hip cannot be obtained by gentle manipulation open reduction is accomplished and the position is maintained by nail.

The degree of slipping of the epiphysis is determined by the distance that the head has slipped from the superior outline of the femoral neck as seen in the lateral view of the hip. If this distance is 1 cm

or more the slip is considered to be pronounced and to require open reduction. If it is less than 1 cm. it is considered minimal and no reposition is required but the hip is nailed *in situ*.

Open reduction is accomplished by means of the Smith Petersen intrapelvic approach and the epiphysis is separated from the femoral neck at the epiphyseal plate with a curved osteotome. Once separated the osteotomy is left in place to serve as a skin and the reduction is done by traction on the leg in flexion, internal rotation and finally abduction and extension of the femur. A separate lateral incision is made for the nailing. Follow-up care consisted of balanced traction for from 10 to 12 days. Two weeks after operation the patients were gotten up on crutches. Postoperative plaster splints were discarded because there was a distinct tendency toward stiffened hips. Nonweight bearing walking caliper hip splints used with high sole on the good side have also been discarded because of the belief that such a brace threw excessive strain on the good hip. The built up shoe puts excessive strain on the good hip and the possibility of a slip of the contralateral hip must always be kept in mind. The use of crutches alone was therefore advised for the first 3 months.

The author presents a report of his survey of 31 slipped capital femoral epiphyses of which 22 were treated with the three flanged nail, 16 of these required arthroscopy, 1 reduction prior to nail, 3 cases were of the cut type.

There were no signs of aseptic necrosis and in only 3 cases were there a very mild traumatic arthritis. These cases were in young those in which open reduction was required and the condition in 1 case may have been caused by incomplete reduction. An average 90 per cent of normal hip function was obtained when the hips were nailed *in situ*, and 92 per cent of normal function was obtained when open reduction was required. These figures are based on observation periods of about 3 years. The results are the best so far reported. *VERMONT COLLEGE MEDICAL*

Indications and Results of Surgical Treatment of Monocondylar Fracture of the Femur and Tibial Plateau (Indicazioni e risultati nella cura chirurgica delle fratture monocondilari del femore del piatto tibiale) LEONARDO GUI *Chir. Org. Milano* 1947 3 308.
